ANNOUNCEMENT

The Central Society for Clinical Research and The C. V. Mosby Company have entered into an agreement which provides that *THE JOURNAL OF LABORATORY AND CLINICAL MEDICINE* will be published as the official publication of the Central Society for Clinical Research. Beginning with Volume 32, this issue, the Central Society for Clinical Research will assume editorial direction of the *JOURNAL*.

The Board of Editors will consider for publication manuscripts which record original contributions in the broad fields of clinical investigation and clinical pathology. A "Methods" section will be retained. The works of *all authors* are invited; society affiliations will not prejudice or influence editorial decisions. The current practice of providing prompt publication of articles accepted by the Board of Editors will be continued.

Many of the papers which will appear in the first three issues were approved by the former editorial board.

METABOLIC FUNCTION OF PTEROYLGLUTAMIC ACID AND ITS HEXAGLUTAMYL CONJUGATE

I. HEMATOLOGIC AND URINARY EXCRETION STUDIES ON PATIENTS WITH MACROCYTIC ANEMIA

FRANK H. BETHELL, M.D., MURIEL C. MEYERS, M.D., GOULD A. ANDREWS, M.D.,
ANN ARBOR, MICH., AND MARLAN E. SWENDSEID, PH.D., ORSON D. BIRD, PH.D.,
AND RAYMOND A. BROWN, PH.D., DETROIT, MICH.

THE properties of folie acid as a hematopoietic factor differentiate it clearly from both the dietary extrinsic factor and the antipernicious anemia principle contained in refined liver extracts.¹ Since folie acid occurs in foods almost wholly in conjugated form,² it is pertinent to compare the hematopoietic responses of suitable patients with macrocytic anemia following the administration, in sequence, of the vitamin in the bound and free states. Furthermore, an estimate may be obtained of the ability of such patients to release the vitamin from its conjugate by determinations of the urinary excretion of the free material after the oral administration of the conjugate. Because the terminology applied by different authors to folie acid and related compounds is variable and confusing, the free vitamin, folie acid, henceforth will be designated by its chemical name, pteroylglutamic acid, and the conjugate used in these studies will be referred to as pteroylhexaglutamylglutamic acid (hexaglutamyl conjugate).³ Another conjugate of pteroylglutamic acid has been isolated by Stokstad and co-workers⁴ and termed the fermentation *Lactobacillus casei* factor or pteroyltriglutamic acid.

In a previous communication⁵ we reported that a naturally occurring conjugated form of folie acid was not as effective as the free vitamin in producing hematopoietic responses in two patients with pernicious anemia in relapse and in one patient with macrocytic anemia following subtotal gastrectomy. Observations leading to a similar conclusion have been described by Weleh and associates.⁶ At this time we shall present additional data pertaining to the utilization by patients with pernicious anemia and related macrocytic anemias of the hexaglutamyl conjugate as evidenced by their hematopoietic responses and the urinary excretion of the free vitamin after administration of the conjugate. These studies were initiated by the consideration that in pernicious anemia there is an apparent deficiency of the vitamin, pteroylglutamic acid, which cannot, in most cases, be explained by dietary inadequacy.

The specific disturbances of erythropoiesis (namely, megaloblastic proliferation and defective maturation) which characterize many of the macro-

From the Thomas Henry Simpson Memorial Institute for Medical Research, University of Michigan, Ann Arbor, Mich., and the Research Laboratories, Parke, Davis & Company, Detroit, Mich.

Presented in part at the annual meeting of the Central Society for Clinical Research, Chicago, Ill., Nov. 2, 1946.

Received for publication, Dec. 16, 1946.

cytic anemias have suggested that a common functional derangement was operative in their production. This concept was greatly strengthened by the work of Castle and associates⁷ who demonstrated convincingly the essential role played by diet and by gastric secretion in the maintenance of normal human erythrocyte formation; it received additional support from the observation that a single form of therapy was generally effective in macrocytic anemias of widely varying clinical background. As a consequence, most studies bearing on the etiology of clinically encountered or experimentally produced macrocytic anemia were concerned with attempts to relate the condition under observation to deficiency of a gastric (intrinsic) or a dietary (extrinsic) factor or to some disturbance in the absorption or utilization of the product of their interaction.⁸ Although this theory appeared to be generally consistent with factual observations, its universal application was made difficult by the accumulation of evidence that some cases of macrocytic anemia, particularly those associated with nutritional deficiencies and pregnancy, failed to respond adequately to parenteral administration of concentrated liver principle but showed reversion to normal erythropoiesis when cruder preparations of liver were given either by oral or parenteral routes or when autolyzed yeast was administered by mouth. The existence of a hematopoietic substance in crude liver extracts and yeast, other than the antipernicious factor present in purified liver extracts, was first postulated by Wills and Evans.⁹ They concluded from controlled observations that lack of this substance was responsible for their cases of tropical macrocytic anemia as well as for an experimentally produced macrocytic anemia of monkeys¹⁰ and suggested that a similar deficiency in sprue might result from failure of absorption. They identified the substance tentatively as a part of the vitamin B complex and pointed out that it differed from dietary extrinsic factor if the hematopoietic activity of the latter, in accordance with the theory of Strauss and Castle,³ was limited to a role in the formation of the liver principle.

Day and associates¹¹ recognized independently in monkeys a macrocytic anemia prevented or cured by administration of yeast or liver extracts. They named the curative factor in these materials vitamin M.¹² More recently, Day and co-workers¹³ and also Wilson and associates¹⁴ showed that the deficiency syndrome in monkeys could be successfully treated with purified *L. casei* factor (pteroylglutamic acid). Hogan and Parrott¹⁵ were the first to describe an anemia resulting from a dietary deficiency in chicks. They designated the hematopoietic agent vitamin B₁₂. Vitamin B₁₂ was subsequently isolated¹⁶ and now has been shown to be identical with pteroylglutamic acid.³ A similar nutritional deficiency characterized by leucopenia and anemia has been produced in rats largely as a result of the work of Daft, Sebrell, and their associates.¹⁷

An analysis of the literature dealing with the relative effectiveness of refined liver extracts and cruder preparations of liver, whole liver, or autolyzed yeast in the treatment of human macrocytic anemias was recently published by Watson and Castle.¹⁸ These workers reported four cases of nutri-

tional macrocytic anemia. In three of the patients there was no response to parenterally administered liver extract in dosages effective in the treatment of addisonian pernicious anemia, but there were good hematologic and clinical results when a liver extract was given by mouth. In a fourth patient a response was obtained only when the parenterally administered dose of liver extract was increased ten times. They recognized the presence in crude liver extracts and autolyzed yeast of the hematopoietic substance, described by Wills and Evans,⁹ and suggested for it the designation of "Wills' factor."

The observations of Wintrobe¹⁹ on the effects of brewers' yeast on erythropoiesis in pernicious anemia support the view that patients with this disease may be able to utilize some substance other than the "liver principle." Earlier investigators, to whom Wintrobe refers, demonstrated the effectiveness of yeast, usually given in autolyzed form in the treatment of some cases of pernicious anemia, but Wintrobe first seriously questioned the validity of attributing the hematopoietic effect of yeast exclusively to its extrinsic factor content. His data reveal the variability of responses by patients with pernicious anemia to the administration of yeast.

With the demonstration by several groups of investigators of the effectiveness of pteroylglutamic acid in the treatment of pernicious anemia and other macrocytic anemias,²⁰⁻²⁴ it appeared probable that the activity of crude liver and yeast in the studies referred to previously was due to their content of pteroylglutamic acid in free or conjugated form.

Earlier observations on the therapeutic effectiveness of pteroylglutamic acid in human anemic and leucopenic states were handicapped by lack of availability of the vitamin in pure form or in relatively concentrated amounts. Thus, the inconclusive or negative results obtained by Sharp and associates,^{25, 26} Castle and co-workers,²⁷ Vilter and Spies,²⁸ and Moore and associates²² may be attributed to administration of too small amounts of effective material, as suggested by Sharp, or to the use of material in a form not readily utilizable by persons with pernicious anemia.

CLINICAL MATERIAL AND EXPERIMENTAL PROCEDURE

In the course of this study data were secured from nine patients with addisonian pernicious anemia in relapse and four with other macrocytic (megaloblastic) anemias; of these, two followed gastrectomy, one was probably on a nutritional basis with some features of the nontropical sprue syndrome, and one was associated with chronic diffuse liver disease. Data were also obtained on the urinary excretion of pteroylglutamic acid by three patients with pernicious anemia in liver extract-induced remission. All patients with pernicious anemia fulfilled the diagnostic requirements of macrocytic anemia with characteristic morphologic changes in the peripheral blood, megaloblastic marrow hyperplasia, achlorhydria persisting after parenteral administration of histamine, and ultimate hematopoietic response to treatment with either pteroylglutamic acid or the intramuscular injection of refined liver extract.

Hemoglobin and hematocrit determinations and cell counts were made at regular intervals, using oxalated venous blood, and reticulocyte percentages were obtained daily throughout the period of observation on all patients in relapse. The urinary excretion of pteroylglutamic acid was determined by microbiologic assay using *L. casei*.² No evidence was obtained of the excretion of the conjugated vitamin as such. While studies were being carried out, the subjects were given a low protein, meat-free diet of adequate caloric value.

The procedure employed in performing the clinical studies, with some individual modifications, was as follows. Urine collected and suitably preserved during the first twenty-four hours of study was used for the quantitative determination of urobilinogen.²⁹ Subsequently, for at least two days, the urinary output of pteroylglutamic acid was measured while the patient received the standard diet without medication. A yeast concentrate supplying known amounts of hexaglutamyl conjugate was then given daily for varying periods up to fourteen days, followed by the administration of synthetic pteroylglutamic acid^{30, 31} in a dosage equivalent to that of the vitamin present in the conjugate. In one case a period of conjugate administration was followed by one in which the same yeast concentrate was given after incubation with a specific enzyme capable of liberating the vitamin from its bound form. The properties of the hexaglutamyl conjugate are described in the accompanying communication in which are reported the results of urinary excretion studies on normal individuals.³²

CASE REPORTS AND EXPERIMENTAL RESULTS

I. Hematopoietic Responses of Patients With Macrocytic Anemia Following the Administration of Conjugated and Free Pteroylglutamic Acid

CASE 1.—H. W., a 63-year-old white man, fulfilled all diagnostic criteria of pernicious anemia and had had the disease for approximately four years. Although the anemia was severe the patient appeared to be in fairly good nutritional state, was ambulatory, and had no complicating conditions. He complained of numbness and tingling of the extremities but had no disturbance of gait and no objective signs of central nervous system degeneration. During the preliminary period of observation and diet standardization it became advisable to give the patient a transfusion because of extreme weakness and progression of anemia. Accordingly, 500 c.c. of whole blood were administered and subsequently he was given daily a yeast concentrate containing the equivalent of 4 mg. of pteroylglutamic acid as hexaglutamyl conjugate. After he had received this material for ten days with no hematopoietic response, treatment was changed to synthetic pteroylglutamic acid in a daily oral dose of 4 milligrams. The hematologic data obtained on this patient are shown in Table I.

CASE 2.—N. J., a 56-year-old white man, was first admitted to the Simpson Memorial Institute in 1936, when the diagnosis of pernicious anemia was made and he responded in the expected manner to the parenteral administration of liver extract. During the intervening ten years the patient had received liver therapy very irregularly and none had been taken for several months prior to the present admission. The diet appeared to be adequate particularly with respect to protein from animal sources. There were no subjective or objective manifestations of nervous system involvement. The patient was not given a transfusion, and after a preliminary period without treatment he was given the hexaglutamyl conjugate in a dosage equivalent to 4 mg. of the free vitamin. A small increase in reticulocytes occurred which, since this patient at the same time showed a

slight rise in urinary excretion level of pteroylglutamic acid, probably indicates some ability to liberate and utilize the conjugated form of the vitamin. During the second part of the experiment the patient received the same yeast concentrate in identical dosage but previously incubated with a specific conjugase derived from hog kidney. This enzyme has been shown to liberate pteroylglutamic acid from the hexaglutamyl conjugate.² The quantity of hog kidney tissue employed and the method of preparation of the conjugase-containing extract were such as to render it extremely unlikely that any response could be attributed to the presence of antipermeious substance in hog kidney. A suboptimal but definite reticulocyte rise occurred during administration of this material, together with a substantial increase in erythrocytes and hemoglobin and decided clinical improvement. Hematologic data obtained on this patient are presented in Table II.

CASE 3.—H. P., a 65 year old white man, underwent subtotal gastrectomy for adenocarcinoma of the stomach three years before the present admission. Approximately seven-eighths of the stomach was removed. There were no evidences of metastases at the time

of the operation or later. Gradual development of weakness and fatigability occurred about one and one-half years before the current admission. Although the dietary habits were modified by the necessity of taking frequent small meals, largely in order to avoid symptoms of postgastrectomy hypoglycemia, the quality of the food was not restricted and, since the patient had received detailed dietary instructions following the operation, the diet may be assumed to have been somewhat better than the average for a person of his age and economic status. The patient's symptoms were attributable to the anemia and physical examination was negative except for pallor and moderate underweight. The urine was negative except for 1 plus protein and the stool examination revealed no occult blood and no evidence of parasitism. This patient received yeast concentrate supplying the hexaglutamyl conjugate in a daily dosage equivalent to 2.3 mg. of the free vitamin for eight days with no hematopoietic response. Subsequently he was given synthetic pteroylglutamic acid in the same dose. There was only a slight increase in reticulocyte percentage but a definite rise in erythrocytes and hemoglobin. Hematologic data are shown in Table III.

CASE 4.—E. B., a 76-year-old white man, fulfilled the diagnostic criteria of pernicious anemia and had had symptoms for approximately two years. The diet had been deficient particularly with respect to meat and vegetables, but the patient had included in his average daily intake six slices of bread, one egg, and one quart of milk. He had lost about 7 pounds during the eight months preceding the admission to the hospital. He had no gastrointestinal complaints other than moderate anorexia. Numbness and tingling of the feet with some difficulty in walking in the dark had been present for three months. The only objective neurologic abnormalities were moderately increased deep reflexes of upper and lower extremities, bilateral, and slight impairment of vibratory sense in the feet. Treatment with yeast concentrate supplying hexaglutamyl conjugate in daily dosage equivalent to 5 mg. of pteroylglutamic acid was carried out for eight days with no hematopoietic response. Since other metabolic studies were performed subsequently on this patient, it was not possible to demonstrate an initial response to administration of the free vitamin alone. However, for three months the patient has received pteroylglutamic acid, 5 mg. daily by mouth, without other medication, and during this period the blood values reached normal levels and remission has been well maintained. Hematologic data obtained on this patient are shown on Table IV.

CASE 5.—G. L., a 76-year-old white man, complained chiefly of diarrhea and swelling of the legs. Beginning about four years prior to admission to the hospital the diarrhea at first had been periodic, but for the last five months it had been constant with from three to six watery yellow stools each day. Swelling of the legs had been present and had progressed for more than one year. Weakness, ease of fatigue, and dyspnea on exertion had developed over a period of five years, and during this time the patient noted numbness

and tingling of the lower extremities, ataxia, and a burning sensation in his feet. Periodic soreness of the tongue had been present for about one year. He also complained of burning and itching of the eyes. The diet was grossly inadequate, consisting chiefly of bread and potatoes. The patient prepared his own food and bought one-half pound of hamburger each week. No other meat was taken and the diet contained very little milk, eggs, green vegetables, or fruit. His appetite was poor and the patient's weight had decreased from a maximum of 155 pounds to 117 pounds on admission and 100 pounds after diuretic therapy.

Examination revealed the following signs: severe emaciation; dry, shiny skin with many follicular keratoses and irregular areas of brownish pigmentation; vascularizing keratitis and corneal opacities; fissures at the angles of the mouth; a smooth, magenta tongue with some fiery red areas; and other evidences of riboflavin and nicotinic acid deficiency. There was generalized arteriosclerosis. The blood pressure was 108 systolic and 70 diastolic. The heart findings were not abnormal and the lungs were clear except for rales at the bases. The abdomen was negative. Pronounced pitting edema of the lower extremities was present bilaterally. Knee and ankle jerks were not elicited, vibratory sense was absent below the knees, and sense of motion and position was impaired. There was calf muscle tenderness and light pressure over the toes elicited a sensation of burning.

Macrocytic anemia of moderate degree was present. Stereal marrow aspiration revealed increased and disordered erythropoiesis with numerous megaloblasts. Histamine refractory achlorhydria and absence of pepsinogen were demonstrated. Total serum proteins were 6.5 Gm. per 100 c.c. with albumin globulin ratio of 1.6. All other laboratory examinations including hepatic and renal function tests gave essentially normal results. Roentgen study of the gastrointestinal tract revealed profound small bowel dysfunction. "At no point in the course of the small intestine can one find normal bowel pattern. Irregularity of lumen width is pronounced. 'Puddling' of barium is equally obvious." (Dr. F. J. Hodges.)

This patient received the same yeast concentrate as those discussed previously supplying the hexaglutamyl conjugate in a daily dose equivalent to 5 mg. of pteroylglutamic acid. During an eight day period of conjugate administration little evidence of a reticulocyte response was noted although a significant increase in erythrocytes and hemoglobin occurred (Table V). Moreover, as will be shown later, the patient excreted a relatively large amount of free vitamin during administration of the yeast concentrate. Although this patient obviously suffered with multiple nutritional deficiencies and small bowel disease, it is not possible to exclude Addisonian pernicious anemia in view of the achylia gastrica. However, his failure to improve over a period of three months, with persistence of anemia, diarrhea, eye and tongue changes, and further weight loss, strongly suggests that the pathologic process is quite distinct from that responsible for pernicious anemia. Little or no improvement has followed therapy with pteroylglutamic acid in daily doses of

15 mg. by oral and parenteral routes of administration, large doses of refined and crude liver extracts by intramuscular and intravenous injection, and the intravenous administration of plasma and vitamin B fractions. The nervous system manifestations in this case are not severe and may be entirely attributable to peripheral nerve disease. There is no evidence of active infection to explain the failure of response to specific therapy.

CASE 6—G. W., a 74 year old white man, developed symptoms of anemia six years prior to admission to the hospital. He was treated with injections of liver extract and improved, but treatment became increasingly irregular. Numbness and tingling of the feet had been present for eighteen months and periodic burning of the tongue for six months. Weakness gradually became so severe that he was unable to leave his home. Although his appetite had been poor for three months and he had lost about 10 pounds during this period, the diet did not appear to be qualitatively seriously deficient. The patient was fairly well nourished but extremely pale. The tongue was smooth with reddening along the lateral margins. Patellar reflexes were diminished and vibratory sense was absent over the left foot and ankle, elsewhere over the lower extremities it was greatly decreased. In other respects the physical findings were essentially normal. The results of laboratory studies, including achlorhydria and megaloblastic marrow reaction, were characteristic of pernicious anemia. This man received a yeast concentrate differing from that given to the patients previously discussed in that by *in vitro* test it possessed only one seventh as much conjugase inhibitor activity. It has been shown by Bird and associates²² that yeast extracts contain a strong inhibitor for pteroylhexaglutamylglutamic acid conjugase and that this inhibitor is gradually removed during fractionation of yeast extract in the prepa-

ration of pure conjugate. A hematopoietic response was obtained during administration of this yeast concentrate supplying as conjugate the equivalent of 4 mg. of pteroylglutamic acid daily. No second reticulocyte increase followed the oral administration of the same dose of the free vitamin (Table VI).

CASE 7.—T. K., a 69-year-old white woman, fulfilled all diagnostic criteria of pernicious anemia and had first experienced symptoms of anemia five months previously. Numbness and tingling of the feet had been present for about five years with no ataxia or disturbance of gait. The patient was moderately obese and had no evidences of nutritional deficiency. The tongue was reddened and smooth along the lateral margins. Patellar reflexes were diminished and vibratory sensation was impaired over both lower extremities. This patient denied having received any form of antianemia therapy prior to admission, and she was observed in the hospital for fourteen days before treatment was instituted. During this period no hematopoietic response occurred but on the day treatment was started an increase in reticulocyte percentage was observed. The subsequent course of the reticulocyte rise was of a type that strongly indicated a specific response to the material administered, but the high initial value suggested that the marrow at the time of institution of therapy was in a reactive state. She received the same yeast concentrate as that given to G. W. (Case 6) in daily dosage equivalent to 4 mg. of pteroylglutamic acid, and later suggestive but not conclusive evidence was obtained of a second reticulocyte response to treatment with the free vitamin (Table VII).

The data obtained from observations of the hematopoietic responses of Cases 1 to 7 indicate that patients with proved pernicious anemia in relapse are unable to utilize in any appreciable degree the hexaglutamyl conjugate of pteroylglutamic acid when the material is supplied orally together with relatively large amounts of a conjugase inhibiting substance. The responses obtained when a conjugate source containing less enzyme inhibitor was administered suggest that the defective utilization of natural forms of pteroylglutamic acid by patients with pernicious anemia is quantitative and probably varies with the individual patient.

II. Urinary Excretion of Pteroylglutamic Acid During Administration of the Hexaglutamyl Conjugate and the Free Vitamin to Patients With Macrocytic Anemia in Relapse

In this study determinations of the twenty-four-hour urinary excretion of pteroylglutamic acid were performed on the patients previously discussed (Cases 1 to 7) and on six additional patients who could not be tested for hematopoietic responses either because of their relatively high initial erythrocyte values or their unwillingness to submit to protracted courses of therapy. The data secured from the urinary assays on all of the subjects are compiled in Table VIII. Brief abstracts of the six additional cases follow.

CASE 8.—O. B., a 39-year-old white man, had had periodic soreness of the tongue for three years and symptoms of anemia for four months. The clinical and laboratory findings were entirely characteristic of pernicious anemia. The patient had received no previous antianemia therapy. Initial hematologic values were: red cells, 1,500,000 per cubic millimeter; hemoglobin, 6.4 Gm. per 100 c.c.; hematocrit, 19 per cent; mean corpuscular volume, 112 cubic microns; mean corpuscular hemoglobin concentration 33.7 per cent; white cells, 4,750 per cubic millimeter. Clinical and hematologic remission was attained while the patient was receiving pteroylglutamic acid, 5 mg. daily.

CASE 9.—L. P., a 63-year-old white woman, had been treated for pernicious anemia with striking symptomatic improvement five years previously. She had had no treatment for about four years prior to the admission. She presented the characteristic features of pernicious anemia with initial blood values as follows: red cells, 900,000 per cubic millimeter; hemoglobin, 3.6 Gm. per 100 c.c.; hematocrit 11.0 per cent; mean corpuscular volume, 122 cubic microns; mean corpuscular hemoglobin concentration, 32.8 per cent; white cells, 3,050 per cubic millimeter. Because of the severity of the anemia a single blood transfusion was given. The patient has subsequently attained complete clinical and hematologic remission while receiving pteroylglutamic acid, 5 mg. by mouth daily.

CASE 10.—H. B., a 71-year-old white woman, had symptoms of weakness, numbness and tingling of the extremities, and soreness of the tongue of approximately one year's duration. She had macrocytic anemia, megaloblastic marrow reaction, and histamine refractory achlorhydria. An initial hematopoietic response was obtained during oral administration of pteroylglutamic acid, 5 mg. daily, but complete remission was induced by intramuscular injection of refined liver extract, 15 units weekly. The hexaglutamyl conjugate was not given to this patient, and urinary excretion data are limited to observations during the administration of the free vitamin. The initial hematologic values were as follows: red cells, 1,700,000 per cubic millimeter; hemoglobin, 6.4 Gm. per 100 c.c.; hematocrit, 20 per cent; mean corpuscular volume, 118 cubic microns; mean corpuscular hemoglobin concentration, 32 per cent; white cells, 4,800 per cubic millimeter.

CASE 11.—D. R., a 55-year-old white woman, had onset of numbness and tingling and disturbances of gait eight months previously. Soreness of the tongue had been present for several weeks. Examination revealed evidence of moderately advanced posterolateral column degeneration. Quantitative blood cell changes were minimal, but definite variations in red cell morphology were observed including anisocytosis and macrocytosis. Histamine refractory achlorhydria was demonstrated. After excretion studies were completed, decided symptomatic improvement and restoration of blood values to normal followed treatment with refined liver extract by intramuscular injection. The initial hematologic data were as follows: red cells, 4,100,000 per cubic millimeter; hemoglobin, 13.3 Gm. per 100 c.c.; hematocrit, 41 per cent; white cells, 4,850 per cubic millimeter.

CASE 12.—T. N., a 56 year old white man, developed macrocytic anemia five years after total gastrectomy for gastric ulcer. The blood cell values rapidly became normal while the patient was receiving pteroylglutamic acid, 5 mg. daily by mouth.

CASE 13.—E. J. B., a 64 year old white woman, had macrocytic anemia of mild degree associated with evidences of chronic diffuse liver disease. For one year she had received refined liver extract, 15 units intramuscularly every one to two weeks, and some improvement in blood values had followed this therapy. Shortly before admission to the hospital the patient had an exacerbation of the hepatic disorder with rapidly developing painless jaundice and enlargement of the liver, associated with evidences of increased hepatic dysfunction obtained by laboratory tests. It was during this period of heightened activity of the disease process that pteroylglutamic acid excretion studies were performed. Subsequently the patient recovered from the acute exacerbation of the illness and at present is much improved.

The excretion of free vitamin during oral administration of the hexaglutamyl conjugate to patients with pernicious anemia in relapse and macrocytic anemia following gastrectomy was quite variable. Nevertheless, as has been shown by the percentage calculations on Table VIII, only a small fraction of the dose was excreted in the urine, whereas a much greater part of the orally administered free vitamin was excreted. Comparison of the data obtained on these subjects with those secured during similar studies on normal persons reveals that the patients with pernicious anemia and postgastrectomy macrocytic anemia have much lower excretion levels of pteroylglutamic acid during conjugate administration.³² Although a difference in excretion values during administration of the free vitamin to these patients and to the normal subjects was also observed, it was much less than that found when the conjugate was given. Moreover, as

illustrated by Cases 1 and 10, continuous administration of the free vitamin was associated with excretion values increasing to levels equaling those obtained on normal subjects. This was not observed when the hexaglutamyl conjugate was fed continuously in a yeast concentrate possessing strong conjugase inhibiting activity (Cases 3 and 9). Case 4 (E. B.) who also received the conjugate showed a definite increase in excretion of the free vitamin, but the maximum level attained after six days of administration was less than the lowest value observed in the group of normal subjects.

Special consideration must be given to the excretion values obtained in Cases 5, 6 and 7. They will be reviewed together with the pertinent hematologic data in the discussion to follow.

In Case 13, macrocytic anemia associated with liver disease, very low excretion values for pteroylglutamic acid were observed after both conjugate and free vitamin administration.

III. The Effect of Liver Extract (Parenteral) on the Urinary Excretion of Pteroylglutamic Acid During Administration of Its Hexaglutamyl Conjugate to Pernicious Anemia Patients

Refined liver extract was given by intramuscular injection to a patient with pernicious anemia in relapse who had received no previous antianemia therapy (Case 8). The dose employed was 15 U. S. P. units contained in 1 c.c. given on each of three consecutive days. Hexaglutamyl conjugate was taken orally for three days before institution of liver extract therapy and during the period of its administration. No significant change in the excretion levels of pteroyl-

glutamic acid was observed (Table IX). A similar study was carried out on another patient with pernicious anemia (Case 1) after the administration of synthetic pteroylglutamic acid, 10 mg. daily by mouth for seven weeks. During the period of pteroylglutamic acid therapy the erythrocyte count increased from 2,100,000 to 3,300,000 per cubic millimeter. Refined liver extract was injected intramuscularly for six consecutive days in a daily dosage of 15 U. S. P. units except that on the second day of treatment the patient received 45 units. In this case also no change in the excretion of free vitamin was observed during simultaneous administration of hexaglutamyl conjugate and liver extract (Table X).

Three patients with pernicious anemia in liver extract-induced remission were studied with respect to their excretion of free vitamin during administration of hexaglutamyl conjugate.

CASE 14.—W. M., a 72-year-old white man, was found to have pernicious anemia thirteen years previously. He has been under continuous observation since then, has received parenteral liver extract regularly, and has never been in relapse.

CASE 15.—N. M., a 64-year-old white woman, was given the diagnosis of pernicious anemia fifteen years before the present studies. Throughout the period she has been treated with parenteral liver extract and the hematopoietic values have been maintained within normal limits.

CASE 16.—A. G., a 66-year-old white man, presented the diagnostic features of pernicious anemia sixteen years previously and for a number of years was treated with desiccated stomach. For the past five years he has received intramuscular injections of liver extract. The patient has always been irregular in following the treatment schedule, and although he has never been in severe relapse, the blood cell values have frequently indicated that therapy was inadequate. When pteroylglutamic acid excretion studies were undertaken the erythrocyte count was 4,100,000 per cubic millimeter, hemoglobin 13.5 Gm. per 100 c.c. and hematocrit 44.5 per cent.

All three of these patients received their initial diagnoses at the Simpson Memorial Institute on the basis of clinical and hematologic features of pernicious anemia, histamine refractory achlorhydria, and subsequent response to antipernicious anemia therapy.

After a preliminary period during which the patients received the standard low protein diet and base line excretion values for pteroylglutamic acid were obtained, they were given the hexaglutamyl conjugate in a daily dose equivalent to 4 mg. of the free vitamin. The source of conjugate was the yeast concentrate possessing strong enzyme inhibiting activity. The last injection of liver extract had been given to these patients about one week previously and none was administered during the excretion studies. The urinary values for pteroylglutamic are presented on Table XI.

It appears to be significant that the excretion levels of pteroylglutamic acid, during the preliminary period when they received the standard diet only, were higher in these patients than in those who were studied during relapse. The base line excretion values of the patients in liver extract-induced remission equal those observed in normal subjects.³² The excretion of free vitamin during the period of conjugate administration was greater in the patients in remission than in any of the patients with proved pernicious anemia in relapse who received the same yeast concentrate (Table VIII).

DISCUSSION

It may be presumed that the excretion of pteroylglutamic acid after conjugate administration is dependent upon several factors, aside from renal impairment. These are: (1) the liberation of the vitamin from the conjugate, (2) its absorption from the alimentary tract, (3) the extent of tissue deficiency, and (4) the presence and functional status of tissue enzyme systems required for pteroylglutamic acid utilization.

In pernicious anemia three of these factors may be operative in varying degrees. Liberation of the free vitamin may be adversely affected by defective intestinal conjugase activity aggravated by the presence of enzyme inhibiting substances. The extent of tissue deficiency may influence the retention of absorbed vitamin and so inversely affect its excretion rate. The status of cellular enzyme systems may govern the capacity of the tissues to utilize the vitamin.

The patients in this series who received the hexaglutamyl conjugate together with relatively large amounts of enzyme inhibitor exhibited little or no hematopoietic response. The low excretion levels of pteroylglutamic acid, therefore, may be attributed largely to deficient conversion of the conjugate to the free form. Case 6 (G. W.) who received a conjugate in a preparation with low inhibitor content had moderately high initial and subsequently increasing levels of vitamin excretion. This observation together with the definite but suboptimal hematopoietic response suggests that a significant amount of pteroylglutamic acid was liberated and absorbed but that in spite of tissue need, as shown by the severity of the anemia, there was imperfect utilization of the vitamin. Case 7 (T. K.), at the time of institution of therapy with the same conjugate as that given in Case 6, showed evidences of spontaneous erythrocyte regeneration. The initial reticulocyte percentage was 5.0 and the rise during treatment was rapid, reaching a peak of 20.0 per cent on the eighth day. This value is greater than the expected maximum reticulocyte peak during adequate oral therapy with liver extract or desiccated stomach for a patient with her pretreatment red blood cell count.³⁴ There can be little doubt that the increase in reticulocytes and total number of circulating red cells, observed in this patient, represents a response to the material administered. The low excretion values for pteroylglutamic acid, as shown on Table VIII, although apparently inconsistent with the observations on other patients in this series, may be attributable to a high degree of tissue deficiency and unusually efficient cellular utilization of the liberated and absorbed vitamin. This concept is supported by the observation in this case of exceptionally low vitamin excretion levels during administration of synthetic pteroylglutamic acid, in the presence of continued hematopoietic response.

Case 5 (G. L.) was discussed earlier with emphasis upon the clinical evidences of multiple nutritional deficiencies refractory to specific therapy. There appear to be adequate grounds for considering this case as one of probable nutritional macrocytic anemia rather than true pernicious anemia. The excretion of unusually high levels of free vitamin during administration of a source of conjugate possessing strong conjugase inhibiting activity is proof of

absorption of the material from the alimentary tract in spite of the small bowel dysfunction and diarrhea. The failure to obtain a sustained hematopoietic response to the subsequent parenteral administration of pteroylglutamic acid and crude and refined liver extracts and the lack of therapeutic effect of large doses of thiamine, riboflavin, and nicotinic acid, administered both orally and parenterally, indicate that in this patient irreversible tissue changes have occurred probably relating to cellular enzyme activity.

These observations suggest that in cases of nutritional macrocytic anemia, even though complicated by extensive disturbances of small bowel function, the liberation and absorption of conjugated pteroylglutamic acid in the presence of conjugase inhibitor are not necessarily impaired as they appear to be in Addisonian pernicious anemia.

Some information relative to a possible role of the intrinsic factor may be afforded by the studies on the two patients with macrocytic anemia following gastrectomy (Cases 3 and 12). The patient (Case 3) on whom hematologic data were obtained resembled those with true pernicious failure in the failure to respond to the administration of the hexaglutamyl conjugate. Neither of the gastrectomy patients excreted increased amounts of pteroylglutamic acid when they were given the conjugate. These results indicate that the stomach may be concerned with the liberation of the conjugate and lead to the suggestion that the intrinsic factor, although not itself capable of converting the hexaglutamyl conjugate to the free form,⁶ may act enzymatically as an anti-inhibitor.

At this time it is possible only to speculate on the reasons why persons with pernicious anemia in liver extract-induced remission excrete larger amounts of pteroylglutamic acid than those in relapse, either when they are receiving a standard diet or during administration of relatively large amounts of a naturally occurring conjugate of the vitamin. The increased excretion rate observed in remission may be due either to a lessened state of tissue deficiency or to more efficient liberation of the vitamin from its conjugated form. However, both hypotheses may be true, since correction of a tissue deficiency by means of refined liver extract, containing very small quantities of pteroylglutamic acid, implies more effective utilization of natural forms of the vitamin. It should not be assumed, however, that the activity of liver extract in bringing about remission in pernicious anemia is limited to enhancing the availability of dietary sources of pteroylglutamic acid. The observation that pteroylglutamic acid, administered either orally or parenterally, is not equally effective in inducing remissions in all patients with pernicious anemia and that it may have no effect on the combined system degeneration frequently associated with this disease³⁵ indicates that the action of liver extract is more complex than simply to relieve a conditioned nutritional deficiency of pteroylglutamic acid. The rapidity of therapeutic response to the injection of refined liver extract exhibited by severely ill patients is quite unrelated to their dietary intake and must be attributed to a direct effect upon tissue metabolism. The observations of many investigators of chronic nutritional deficiency states demonstrate that replacement therapy even with excessive amounts of the

deficient nutritive may be ineffective or only partially effective in re-establishing normal cellular metabolism. Moreover, the protean manifestations of pernicious anemia, and in particular the variable degree of central nervous system involvement found in patients with this disease, suggest that a complex type of cellular enzyme disturbance may exist and that the action of the liver principle in restoring normal pteroylglutamic acid metabolism constitutes but one of its therapeutic effects.

SUMMARY AND CONCLUSIONS

Pteroylglutamic acid (folic acid) and its hexaglutamyl conjugate were given orally to sixteen patients. The series included nine patients with pernicious anemia in relapse, two with macrocytic anemia following gastrectomy, one with chronic liver disease associated with macrocytic anemia, one with macrocytic anemia believed to be due to nutritional deficiency, and three with pernicious anemia in liver extract induced remission.

The hematopoietic responses were observed and the urinary excretion of pteroylglutamic acid was measured during the administration of the conjugated and free vitamin.

Three patients with pernicious anemia in relapse and one patient with macrocytic anemia following gastrectomy exhibited little or no evidence of erythrocyte regeneration when given the hexaglutamyl conjugate in a yeast concentrate containing strong conjugase inhibiting activity. Significant responses occurred when these patients received either equivalent doses of synthetic pteroylglutamic acid or the yeast concentrate after incubation with an enzyme preparation which liberated the free vitamin from its conjugated form.

Two patients with pernicious anemia in relapse had definite hematopoietic responses when they were given the equivalent of 5 mg. daily of pteroylglutamic acid as the hexaglutamyl conjugate in a yeast concentrate containing relatively little enzyme inhibitor.

The patient with probable nutritional macrocytic anemia showed a sub-optimal response to the administration of the yeast concentrate with strong conjugase inhibiting activity.

Determinations made prior to the institution of therapy revealed that the urinary excretion of pteroylglutamic acid was lower in patients with macrocytic anemia than in normal subjects or patients with pernicious anemia in liver extract-induced remission.

In patients with pernicious anemia, postgastrectomy macrocytic anemia, and liver disease, the urinary excretion of free vitamin after the oral administration of conjugate with large amounts of inhibitor was much less than the level obtained in normal subjects. One patient with probable nutritional macrocytic anemia excreted the vitamin in amounts comparable to normal subjects.

In one patient with pernicious anemia previously untreated and in another who had been receiving treatment with pteroylglutamic acid without production of complete remission, the simultaneous administration for short periods of refined liver extract by intramuscular injection and the hexaglutamyl con-

jugate by mouth was not followed by increased pteroylglutamic acid excretion above the levels which had been observed when the conjugate was given alone. On the other hand, the administration of conjugated vitamin to three patients with pernicious anemia in liver extract-induced remission was followed by the excretion of the free material in amounts approximately equal to those obtained in normal subjects.

It is concluded that patients with pernicious anemia in relapse and post-gastrectomy macrocytic anemia cannot readily utilize for hematopoiesis a naturally occurring conjugate of pteroylglutamic acid although they respond promptly to administration of the free vitamin. This defect is not absolute and varies in different patients. Inability to utilize the conjugated vitamin appears to depend, at least in part, upon a conjugase inhibiting substance present in natural sources of conjugate.

Determination of the urinary excretion of pteroylglutamic acid after conjugate administration provides an index of the ability to liberate the free vitamin from its conjugated form.

One of the pharmacologic actions of the liver principle may be the correction of the metabolic defect in the utilization of naturally occurring conjugated forms of pteroylglutamic acid.

METABOLIC FUNCTION OF PTEROYLGLUTAMIC ACID AND ITS HEXAGLUTAMYL CONJUGATE

II. URINARY EXCRETION STUDIES ON NORMAL PERSONS. EFFECT OF A CONJUGASE INHIBITOR

MARLAN E. SWENDSEID, PH.D., ORSON D. BIRD, PH.D., RAYMOND A. BROWN,
PH.D., DETROIT, MICH., AND FRANK H. BETHELL, M.D., ANN ARBOR, MICH.

THE evidence that pteroylglutamic acid by virtue of its role in erythrocytogenesis¹ is an essential factor in human nutritional economy gives emphasis to a study of the metabolic function of this vitamin. Since pteroylglutamic acid occurs in plant and animal tissues in a conjugated form,^{2, 3} such a study must necessarily attempt to delineate the physiologic significance of conjugate in relation to free vitamin and the factors governing conjugate cleavage.

The present communication is concerned with the urinary excretion levels of pteroylglutamic acid (PGA) on normal subjects after the administration of the vitamin both in the free form and as yeast concentrates of the hexaglutamyl conjugate. It was found that there are substances present in certain yeast extracts which lower the expected vitamin excretion rate following conjugate administration, results that are interpreted as evidence of the *in vivo* action of inhibitors on conjugate conversion.

Bird and associates⁴ have reported from the results of their *in vitro* studies on the cleavage of hexaglutamyl conjugate by the enzyme pteroylglutamic acid (PGA) conjugase that there was a substance present in natural sources (that is, yeast extracts) which caused enzyme inhibition.

The conjugate of pteroylglutamic acid used in this investigation was the peptide, pteroylhexaglutamylglutamic acid. This conjugate has been isolated in crystalline form from yeast,⁵ and either it or a conjugate of similar microbiologic activity is widely distributed in both plant and animal tissues.³ For example, we have found⁶ that over 90 per cent of pteroylglutamic acid in the leucocytes and their precursors occur as this type of conjugate. The only other known conjugate is pteroyltriglutamic acid or fermentation factor.^{7, 8} Spies⁹ has reported a single patient with pernicious anemia in relapse who responded to the intramuscular injection of this material. However, there is no evidence on the basis of differential microbiologic assays⁶ that this conjugate has a general natural distribution, and hence it would appear that it may not be of practical nutritional significance.

From the Research Laboratories, Parke, Davis & Company, Detroit, Mich., and the Thomas Henry Simpson Memorial Institute for Medical Research, University of Michigan Medical Schools, Ann Arbor, Mich.

Received for publication, Dec. 18, 1946.

*The hexaglutamyl conjugate when tested microbiologically has a *Lacto-bacillus casei* activity equivalent to *Streptococcus faecalis* activity; after conjugase treatment *L. casei* and *Str. faecalis* activities are also equivalent but are increased. Pteroyltriglutamic acid has an *L. casei* activity higher than its *Str. faecalis* activity; after conjugase treatment *Str. faecalis* activity increases while *L. casei* activity remains the same.

EXPERIMENTAL

Seven normal individuals took part in the study. Most of them received separately two hexaglutamyl conjugate concentrates as well as the free vitamin in daily doses equivalent to 4 mg. of pteroylglutamic acid. Each preparation was administered orally for two consecutive days and the treatment periods were spaced at intervals of one to four weeks.

The two hexaglutamyl conjugate concentrates used in this study were prepared from yeast. One of the concentrates* was a much purer preparation than the other and contained no conjugase inhibitor. The other concentrate was a norite eluate of yeast and contained conjugase inhibitor. The inhibitor activity of this concentrate relative to the amount of pteroylglutamic acid present as determined by in vitro tests¹ was approximately one-third the concentration found in the original yeast. To split the conjugate present in this concentrate required thirty-six times as many PGA conjugase enzyme units as were necessary to free an equivalent amount of vitamin from crystalline hexaglutamyl conjugate.

The pteroylglutamic acid content of the urine was determined by microbiologic assay using *L. casei*. In some instances analyses were made following treatment of the urine with PGA conjugase from hog kidney to determine whether the vitamin was excreted in the conjugate form. The methods used for the assay and treatment with conjugase have been described.³

RESULTS

Tables have been set up showing the urinary excretion levels of PGA before and during the daily administration of 4 mg. of pteroylglutamic acid or concentrates of hexaglutamyl conjugate containing the equivalent of 4 mg. of pteroylglutamic acid.

No evidence for the excretion of the vitamin as the hexaglutamyl conjugate was obtained in any of these experiments, including those where the conjugate was administered as such. These results are not included in the tables.

The values for PGA excretion on unsupplemented diets (averages of 2.5 and 2.9 micrograms on consecutive days) are similar to those studies already reported.¹⁰⁻¹² When pteroylglutamic acid was given, about one-third of the 4 mg. dose was excreted in the urine.

When a concentrate of hexaglutamyl conjugate free from conjugase inhibitor was administered, the urinary PGA excretion levels (averages of 1,193 and 1,412 μ g on consecutive days, Table II) were comparable to those obtained when an equivalent amount of the vitamin was given in the free form (averages of 1,266 and 1,288 μ g on consecutive days, Table I). However, the administration of conjugate concentrates containing conjugase inhibitor resulted in urinary PGA excretion values (averages of 153 and 244 μ g on consecutive days, Table II) which were definitely lower than when the free vitamin or conjugate without inhibitor was given.

Average	1,193	1,412	153	244

TABLE III. URINARY PGA EXCRETION IN NORMAL SUBJECTS DURING ADMINISTRATION OF THE VITAMIN OR ITS HEXAGLUTAMYL CONJUGATE WITH A CONJUGASE INHIBITOR SOURCE

SUBJECT	DAILY TREATMENT	URINARY EXCRETION OF PGA (μ G PGA PER 24 HR.)	
		DAY I	DAY II
He	Conjugate (equivalent to 4 mg. PGA) + 30 Gm. Difco yeast extract	110	--
Br	Conjugate (equivalent to 4 mg. PGA) + 30 Gm. Difco yeast extract	76	156
Bi	4 mg. PGA + 30 Gm. Difco yeast extract	1,190	1,030
Sw	4 mg. PGA + 30 Gm. Difco yeast extract	1,350	1,460

To study further the effect of conjugase inhibitor, 30 Gm. of Difco yeast extract as a source of inhibitor was added to the purified conjugate concentrate (the equivalent of 4 mg. of PGA). In two subjects, PGA excretion levels (110 μ g and an average of 116 μ g per twenty-four hours, Table III) were greatly reduced below the values obtained when the conjugate was given alone.

The urinary PGA excretion levels were also determined during the administration of the free vitamin form *together with* a source of conjugase inhibitor. The values for each of two subjects (average 1,110 and 1,465 μ g per twenty-four hours, Table III) were similar to those obtained when the free vitamin alone was administered (Table I).

DISCUSSION

It has been demonstrated that a hexaglutamyl conjugate concentrate containing PGA conjugase inhibitor when administered to normal subjects results in a lower excretion of PGA than when an equivalent amount of a purer conjugate without inhibitors is given. Moreover, when a natural product containing inhibitor is given with this purer conjugate, urinary excretion levels of PGA are greatly reduced. These data are interpreted as evidence that the PGA conjugase inhibitor can act *in vivo* on conjugase enzyme systems to reduce the cleavage rate of the hexaglutamyl conjugate and hence to decrease subsequent urinary excretion of the free vitamin. PGA conjugase inhibitor does not affect the excretion level of pteroylglutamic acid when the vitamin is administered in the free form.

It is very possible that the inhibition of the conjugase enzyme system by a dietary source material as observed in this study occurs in the gastrointestinal tract and that at least one of the resultant effects is on the rate of absorption of the vitamin. Either this inhibitor or an endogenous product of similar nature may also be active in internal metabolic cycles to hold the greater portion of the body pteroylglutamic acid content as a conjugate.

While factors affecting *in vitro* enzyme experiments do not necessarily influence the complex enzyme systems in the body, the possibility must be considered that the same substance inhibits PGA conjugases *in vivo* and hog kidney PGA conjugase *in vitro*.⁴

The implications of this *in vivo* action of PGA conjugase inhibitor are far-reaching. The hexaglutamyl conjugate, the type of compound which serves for the most part as the nutritional source of pteroylglutamic acid, occurs naturally in association with conjugase inhibitor (results of *in vitro* tests). Such substances as liver, yeast, and spinach, which contain relatively large amounts of conjugate, are also high in inhibitor content.¹³ Therefore, from a nutritional and metabolic standpoint, studies involving the role of hexaglutamyl conjugate cannot be considered apart from conjugase inhibitor.

Wright and Welch¹⁰ have stated that, in contrast to other members of the vitamin B group, only a small percentage of the folie acid estimated to be contained in the diet is excreted by normal individuals. It is probable that the data reported here may offer an explanation for this seeming anomaly as regards folie acid in that the action of conjugase inhibitor reduces the rate of cleavage of conjugate to the free vitamin, the form in which pteroylglutamic acid is excreted.

It has been reported that in pernicious anemia there is a lessened ability to utilize conjugated as compared with free pteroylglutamic acid for hemato-poiesis. These experiments with normal subjects led to the consideration that in patients with pernicious anemia the PGA conjugase inhibitor in the hexaglutamyl conjugate concentrates¹⁴ might be a factor influencing conjugate utilization, and evidence supporting this idea has been presented in the preceding paper.¹⁵

SUMMARY

The excretion values of pteroylglutamic acid have been determined for normal persons before and during the daily administration of 4 mg. doses of the vitamin in the free and conjugated forms.

It has been found that for the normal subject given hexaglutamyl conjugate, the urinary excretion levels of pteroylglutamic acid are dependent upon the presence of an exogenous source of conjugase inhibitor. Administering hexaglutamyl conjugate without inhibitor results in PGA excretion levels similar to those obtained following treatment with the free vitamin. Simultaneous administration of conjugase inhibitor and hexaglutamyl conjugate results in lower PGA excretion levels.

THE EFFECT OF THE METHYLATED XANTHINES ON THE CLOTTING TIME OF THE BLOOD

N. C. GILBERT, M.D., FREDERICK DEY, M.D., AND RUTH TRUMP, B.S.
CHICAGO, ILL.

THE methylated xanthines, in one form or another, have been in use for over half a century. In the last two decades they have been used very extensively. In spite of occasional adverse criticism, there is good reason to think, from accumulated experimental and clinical evidence, that they are of very definite therapeutic value. Any contraindication for their use should be examined carefully and critically.

It has been reported recently¹ that the methylated xanthines in experimental animals increased the prothrombin level of the blood and increased its coagulability. It would be assumed that if any such action resulted from their clinical use, abundant evidence of such an effect would have been previously observed and reported. On the contrary, it has been our impression, at least, that the patients using one or another of the xanthines over a long period of time had a longer life expectancy, not a shorter. Our experience has been that of Fahr,² who has had a long and carefully observed experience with these preparations, that heart failure is apparently postponed.

We have accumulated a great deal of data which we will not attempt to present here in detail, but we will choose only enough to show what we consider very clear evidence that the methylated xanthines have no effect in prolonging the clotting time of the blood.

As a measure of the coagulability of the blood, we determined the clotting time, the response of the subject to intravenous heparin, and the prothrombin level. Clotting times were determined by the capillary tube method. The heparin tolerance test has been adequately described and its significance discussed by de Takats.³ By his technique, an initial clotting time is determined and then 10 mg. of heparin are injected intravenously. Clotting times are determined at ten-minute intervals until the initial level of the blood is again established.

Prothrombin times were determined on the whole plasma and the diluted (12.5 per cent) plasma, using the technique of Quick. In order to establish the normal prothrombin time for our laboratory, control determinations were made on ten normal individuals. By our technique, the normal time for whole plasma was found to vary between 11 and 12.5 seconds, with a mean of 12; while the time for dilute plasma, with two exceptions, was between 32 and 38 seconds, with a mean of 34. In dogs the normal prothrombin time for whole plasma was 6 seconds and for the 12.5 per cent plasma it was 13 to 17 seconds. The results are the average of duplicate or triplicate determinations.

For the study of the immediate effect of the methylated xanthines upon clotting activity, normal individuals were admitted to the hospital, and the

Received for publication, Oct. 31, 1946.

coagulability of the blood was determined before and after the administration of the drug. The patients were placed upon a routine, general ward diet. They were treated as ambulatory patients and permitted the freedom of the ward. During the first week in the hospital, daily heparin curves were taken and one or more prothrombin determinations were made. The patients then were given one of the xanthines, usually aminophyllin, either orally or parenterally, and the heparin curves and prothrombin determinations were made at various intervals.

To observe the effect of intramuscular injections, two normal patients were hospitalized and kept under control conditions for the course of the observations. Because of variations of clotting time and the course of the heparin curve, control readings were made for six days. Only two of the curves are plotted in each case. The curves for the other days lay between these two.

Fig. 1.—Heparin curves before and after the administration of intramuscular aminophyllin, grains $7\frac{1}{2}$, on two patients.

Similarly, after administration of the drug, only the curves of the first and the last day are plotted. These are shown in Fig. 1. In the first patient (C.W.) the control prothrombin readings were 12 seconds for the whole plasma and 33 seconds for the dilute plasma. Prothrombin readings were taken every hour for three hours after the first injection of aminophyllin. These readings were, respectively, 12 seconds for the whole plasma and 34 seconds for the dilute plasma; 12 and 34; 12 and 35; and 12 and 34. At the end of five days the prothrombin times were 12 seconds and 34 seconds.

The second patient (M.J.) showed a control prothrombin time of 12 seconds for the whole plasma and 34 seconds for the dilute plasma. The same readings were obtained at the end of six days.

Two normal patients were given intravenous aminophyllin every eight hours for three doses. The coagulation time and the heparin curve are shown in Fig. 2. The prothrombin times did not change from the controls at the end of the three-day period.

Aminophyllin, $7\frac{1}{2}$ grains intravenously, was also administered to three individuals who were not normal, and the prothrombin levels were determined at hourly intervals for three hours and again at six hours after administration. Two of the patients had been on theobromine calcium salicylate for four weeks; the third was a patient with lymphatic leucemia and had had no medication. The results are shown in Table I.

Fig. 2.—Heparin curves before and after the administration of intravenous aminophyllin, grains $7\frac{1}{2}$, on two patients.

Aminophyllin was given to three normal patients in 3 grain doses, three times daily for from fifteen to twenty-eight days. Control prothrombin levels were taken as were heparin curves; prothrombin levels and heparin curves were repeated at intervals of from two days to one week during the administration of the drug. The results were consonant with those obtained in the previous patients and will not be shown in detail. Similar determinations were made on nine patients with cardiac disease who were ambulatory and uncontrolled. These patients took theobromine calcium salicylate, $7\frac{1}{2}$ grains daily by mouth. Normal coagulation times, normal heparin curves, and normal prothrombin levels were present throughout the experiment.

Further experiments were done upon seven dogs. One dog weighing 13 kilograms was given 15 grains of aminophyllin in one dose and was observed for three days. It suffered no ill effects from the large dose. The prothrombin times (in seconds) with the whole and dilute plasma are given in Table II. The coagulation time and heparin curves showed no significant changes from the controls of the previous two days.

Another dog weighing 11.3 kilograms was given 135 mg. of aminophyllin three times a day for two weeks. This dose was chosen in order to duplicate an experiment in which changes in prothrombin time were noted in such an experiment elsewhere. The first control reading and the heparin curve and the last heparin curve at the termination of the experiment are given in Fig. 3. The two prothrombin readings before the experiment were 6 and 15 seconds. During the experiment the prothrombin times varied from 6 and 15 seconds to 6 and 17 and were 6 and 16 on the last day. The other experiments upon dogs were repetitions of the clinical experiments and developed nothing different from the results shown. Aminophyllin was used in six experiments and theobromine calcium salicylate in one. The results throughout these experiments upon animals were in complete accord with those of Quick.⁵

Fig. 3.

Fig. 4.

Fig. 3.—Dog given 135 mg. of aminophyllin three times a day for two weeks. Control heparin curve and heparin curve at termination of experiment.

Fig. 4.—Composite heparin curve derived from averages on patients who had taken methylxanthines for from ten days to twenty years.

In order to determine whether the prolonged administration of the methylated xanthines has any effect upon clotting activity, studies were made of twenty-five patients chosen at random who had been taking one or another of these preparations for from ten days to twenty years. The results are shown in Table III. Heparin curves were taken in each case. A composite curve is shown; it is based upon the arithmetical averages of each period after the administration of heparin (Fig. 4). The two extremes are shown in Fig. 5. In each case the patient had been taking aminophyllin for two years.

Fig. 5.—These two curves represent the two extremes on patients taking aminophyllin over long periods of time. In each case aminophyllin had been taken continuously for two years.

After the foregoing work was done, Seherf and Schlaelman⁶ reported a shortening of prothrombin time following the intravenous administration of aminophyllin and theobromine sodium acetate. Rieben,⁷ on the other hand, reported that he was unable to confirm the work of Link showing the shortening of the prothrombin time to result from the administration of the methylated xanthines.

We are conscious of the conflicting and confusing reports which have appeared on this subject. A very ready recourse is available for determination of the effects of these drugs by following the advice of Hunter to Jenner—"Don't think. Try!" The determination of the coagulation time by the capillary tube method is easily done, requires no special apparatus, and is accurate for clinical purposes. Allowance must be made for normal, minor deviations from day to day, depending upon several variables. Determinations of prothrombin time admit of many errors. This is especially true when different modifications are used which introduce doubtful variables. It would add to the value of comparative studies if a standard method, such as that of Quick, were used. After all, however, the real point, as far as the methylated xanthines are concerned, is whether the coagulation of the blood is or is not hastened. This can readily be determined in any doctor's office.

SUMMARY

A series of experiments were carried out on patients and on animals to determine whether the prothrombin time, the clotting time of the blood, and the heparin curve were in any way changed by the administration of the xanthine drugs. Prothrombin times were determined in the whole plasma and in the dilute plasma. No change was found by either method. Coagulation times were not affected. The heparin curves were either not affected or were improved.

We wish to express our indebtedness to Dr. Armand J. Quick for his kindly help and advice in the methods of determining prothrombin time and in perfecting our technique.

PENICILLIN IN BEESWAX AND PEANUT OIL, A NEW PREPARATION WHICH IS FLUID AT ROOM TEMPERATURE: ABSORPTION AND THERAPEUTIC USE

HAROLD L. HIRSH, M.D., HARRY F. DOWLING, M.D., JEAN J. VIVINO, M.D.,
AND GEORGINE ROTMAN-KAVKA, M.D.
WASHINGTON, D. C.

PENICILLIN is administered by intermittent intramuscular injections more frequently than by any other method. While continuous intravenous and intramuscular infusions may be best for maintaining high concentrations of the antibiotic over a long period of time, they are necessarily restricted to patients who are closely confined. Likewise, oral administration can be used only in the treatment of certain groups of patients, particularly in those with diseases that respond easily and quickly to penicillin. The major disadvantage of administering penicillin intramuscularly in aqueous solution is the necessity for repeating the injections at two- or three-hour intervals. Consequently, several attempts have been made to slow the absorption of penicillin after it is deposited within the muscles; the most successful of these attempts has been the incorporation of the antibiotic in beeswax and peanut oil by Romansky and Rittman.¹ A single injection of 1 c.c. of their preparation, containing 300,000 units of penicillin, is usually followed by therapeutically effective concentrations in the blood for four to twenty-four hours.^{2, 3} There are certain technical difficulties, however, in the administration of this mixture when it is made according to the original formula. The material is in a solid state at room temperature, and in order to liquefy must be heated before it is injected.

We have studied a preparation containing pure penicillin G which is a modification of the original formula. Merek & Company, Inc., from whom it was obtained, state that the procedure employed in its manufacture "alters the physical state of the menstruum and substantially reduces the viscosity at all temperatures."⁴ We found that this material became fluid within fifteen to thirty minutes after it was removed from the refrigerator to room temperature and that it was not necessary to heat it before it was administered. In the present paper we are reporting the results of our study of the absorption of this mixture and of its use in patients with various infections.

STUDIES ON ABSORPTION

Both crystalline sodium penicillin G and purified calcium penicillin G were administered to an equal number of patients. We found no difference between the two salts, except that the sodium penicillin was lighter in color and became fluid more quickly at room temperature. Each cubic centimeter contained

*Stable at room temperature for at least six months.

300,000 units in refined peanut oil containing 4.8 per cent (W/V) of U. S. P. bleached beeswax. It was administered by using separate 18 or 20 gauge needles for withdrawal and for injection. It was found necessary that both the syringes and the needles be *absolutely* dry.

Twenty subjects without any evidence of impaired renal function or of cardiac or hepatic failure were given 300,000 units of the penicillin, contained in 1 c.c. of wax and oil, deep in the gluteal muscles. Eleven patients received the sodium salt and nine the calcium penicillin, but since no differences were observed in the serum concentrations obtained the two preparations will be considered together. Blood for penicillin determinations was taken at three-hour intervals for twelve hours starting twelve hours after injection in sixteen subjects and during the whole twenty-four hour period following injection in four patients. Serum concentrations of penicillin were determined by a modification of the method of Rammelkamp.⁵ The results are shown in Table I. None of the patients had an assayable concentration of penicillin in the serum at twenty-four hours. Five subjects had significant concentrations at twenty hours, ten at eighteen hours, and fourteen at fifteen hours. All but two of the subjects had detectable concentrations of the antibiotic in their serum at twelve hours. Concentrations ranging from 0.625 to 5 units per cubic centimeter of serum were found in four subjects three to nine hours after injection. In two subjects concentrations of 1.25 and 0.156 units per cubic centimeter were found in the serum fifteen and thirty minutes, respectively, after injection.

20				0.625	0.156		0.039	0

Blood was taken on two occasions from one patient who was receiving daily injections of 300,000 units twenty-four hours after a preceding injection, and no penicillin was detectable.

Since significant concentrations of penicillin were found in the serum of most of the subjects studied for only twelve hours following the injection of 300,000 units, it was decided to study the absorption of 600,000 units of penicillin in wax and oil, contained in 2 c.c. of the mixture. Thirty-six subjects

were given either the sodium or the calcium preparation deep in the thigh or gluteal muscles. Blood for penicillin determination was taken at four-hour intervals thereafter for twenty-four hours in four subjects and at the same intervals starting twelve hours after injection in thirty-one patients. The results are shown in Table II. Twelve of the thirty-six subjects studied had assayable concentrations of penicillin in their serum at twenty-four hours, twenty at twenty hours, and twenty-nine at sixteen hours. In only two patients was there no evidence of penicillin in the serum at twelve hours. Concentrations of penicillin ranging from 0.312 to 10 units per cubic centimeter were found in the serum of five subjects four and eight hours after the injections. Two subjects had serum concentrations of 1.25 units per cubic centimeter thirty minutes after administration of the mixture.

Kirby and associates⁶ found that a higher percentage of patients had detectable concentrations of penicillin in their blood at twenty-four hours following subcutaneous injection of 600,000 units of penicillin in beeswax and peanut oil than following intramuscular injection of a similar amount. Consequently, we gave twenty subjects 600,000 units of penicillin, contained in 2 c.c.

CLINICAL STUDY

Thirty-two patients with various infections have been treated with either sodium or calcium penicillin in wax and oil. In Table IV are shown the results of the treatment of these infections and the dosage schedules employed. The seven patients with gonorrhea had previously failed to respond to doses up to 400,000 units of commercial penicillin in aqueous solution and consequently were treated with a single injection of 600,000 units of penicillin in wax and oil. All had clinical and laboratory evidences of prompt and complete cure which were verified by follow-up examinations two, seven, fourteen, and twenty-one days after treatment. Six patients with gonocoeal arthritis were treated with doses of 300,000 to 600,000 units every twelve hours. One patient failed to respond to a course consisting first of 300,000 units and later of 600,000 units given twice a day for a total of fourteen days. No improvement was noted despite the fact that penicillin concentrations of 0.625 unit per cubic centimeter were found in the joint fluid, whereas only 0.039 unit per cubic centimeter were required to inhibit the gonococcus in vitro. There was no response to an additional course of penicillin in isotonic salt solution, 50,000 units intramuscularly every three hours for five days. The patient ultimately recovered coincident with the administration of sulfadiazine.

Two patients with salpingo-oophoritis were treated with penicillin in wax and oil. The causative agent in the case of one patient was the gonococcus; in

TABLE IV. RESULTS OF CLINICAL STUDY OF PENICILLIN IN BEESWAX AND PEANUT OIL

DISEASE	NUMBER OF PATIENTS	PLAN OF THERAPY (UNITS)	RESULTS
Gonorrhea	7	600,000	Recovered
Gonococcal arthritis	6	300,000 to 600,000 once or twice a day for 8 to 10 days	5 Recovered 1 Unimproved
Salpingo-oophoritis	2	300,000 twice a day for 5 days	Recovered
Secondary syphilis	1	300,000 once a day for 16 days	Serologic titer zero 3 months after completion of therapy
Subacute bacterial endocarditis	1	300,000 twice a day for 12 days, then 600,000 once a day for 14 days	No evidence of infection 2 months after completion of therapy
Infections of skin	9	300,000 to 600,000 once or twice a day for 3 to 14 days	Recovered
Erysipelas	1	600,000 once a day for 5 days	Recovered
Otitis media	2	600,000 once a day for 5 to 8 days	Recovered
Tonsillitis and pharyngitis	2	600,000 once a day for 5 days	Recovered
Laryngitis and bronchitis	1	600,000 once a day for 5 days	Unimproved

the other the agent was not identified. Both patients noted marked relief of pain and discomfort within twenty-four hours after treatment was started. The temperature returned to normal within this period of time. Convalescence was uneventful and the drug was discontinued after five days.

One patient with secondary syphilis was given a course of penicillin in wax and oil consisting of 300,000 units once a day for sixteen days for a total of 4,800,000 units. The course of therapy was uneventful, and three months after completion of treatment the patient's serologic titer had fallen to zero.

Penicillin in beeswax and peanut oil was administered to one patient with subacute bacterial endocarditis due to a *Streptococcus viridans*. He made a spectacular response following the initiation of treatment with his preparation in doses of 300,000 units every twelve hours. This was later changed to 600,000 units once a day. The patient made an uneventful recovery following fifty-six days of treatment and has remained free of evidences of infection two months after completion of therapy.

Nine patients with cellulitis and one with erysipelas were treated with doses of 300,000 to 600,000 units once or twice a day for three to ten days with complete resolution of the infection in each case. In one patient the area of cellulitis surrounded a large abscess which was incised and drained. A hemolytic *Staphylococcus aureus* was cultured from the pus. Still another patient developed scarlet fever in addition to the cellulitis, and recovery was uneventful despite the complication.

Two patients with acute catarrhal otitis media and one patient with tonsillitis and pharyngitis caused by a hemolytic streptococcus recovered with the use of this preparation of penicillin in doses of 600,000 units once a day for five

to eight days. The only other therapeutic failure was in a patient with a non-specific laryngitis and bronchitis treated with 600,000 units of penicillin once a day for five days.

DISCUSSION

The injection of 300,000 units of penicillin in wax and oil resulted in concentrations of at least 0.156 unit per cubic centimeter of serum twelve hours after administration in seventeen of twenty patients (85 per cent). An additional patient exhibited a concentration of 0.039 unit per cubic centimeter increasing to 90 per cent the incidence of significant concentrations of the antibiotic in the serum at twelve hours. These concentrations of penicillin have been found to be bactericidal for most penicillin-sensitive organisms. Seventy per cent of the patients studied had serum concentrations of 0.039 unit per cubic centimeter, or more, fifteen hours after the injection: 50 per cent exhibited these concentrations at eighteen hours and 25 per cent at twenty-one hours.

Increasing the dose to 600,000 units resulted in serum concentrations of 0.078 unit per cubic centimeter, or more, at twelve hours in thirty-four out of thirty-six patients (94 per cent). Twenty-nine patients (80 per cent) had effective concentrations of the antibiotic in their serum at sixteen hours and nineteen (54 per cent) at twenty hours. One-third of the patients studied were found to have serum concentrations of penicillin of at least 0.078 unit per cubic centimeter twenty-four hours after injection.

The injection of 600,000 units of penicillin in wax and oil subcutaneously resulted in high concentrations for as long as twenty-four hours after injection in all except one of the patients studied.

The concentrations of penicillin in the blood reported by Kirby and associates³ following the intramuscular injection of 300,000 units of penicillin in beeswax and peanut oil were present for a shorter time than those reported by Romansky and Rittman² who used a similar preparation.

Both of these groups of investigators employed a preparation made according to the original formula devised by Romansky. Our results with the modified formula are essentially the same as those obtained by Kirby and associates.³

Thirty-two patients with various infections amenable to penicillin were treated with this preparation. The results were as satisfactory as those obtained with penicillin administered in aqueous solution or with penicillin made according to the original formula.⁷⁻¹²

Only slight to moderate local pain occurred when the preparation was injected intramuscularly. This discomfort began immediately and usually lasted only a minute or two, very occasionally as long as three or four hours. Most of the patients complained of moderate to marked pain immediately after subcutaneous injection and developed a painful tender nodule which persisted for several days. Eleven days after a subcutaneous injection of 600,000 units of penicillin, one patient developed an area of induration and angioneurotic edema 3 inches in diameter without constitutional symptoms. This subsided within a week on symptomatic measures.

It is obvious that any modification of penicillin which will permit injections to be spaced at twelve- to twenty-four hour intervals will be advantageous, particularly in the case of patients with such diseases as subacute bacterial endocarditis or syphilis who have to be treated for long periods of time. Therapy is simplified in infections which require treatment for several days. This method of treatment is ideal also for patients with gonorrhea since it can be carried out with one injection. The high serum concentrations obtained during the first few hours following injection make it likely that infections caused by organisms which are relatively resistant to penicillin can be treated satisfactorily by proper regulation of the dose and time interval. These advantages have been offset, in the past, by the difficulty inherent in the administration of penicillin in peanut oil and beeswax as prepared by the original Romansky formula. We believe that the modified preparation which we have used eliminates this difficulty in administration, at the same time retaining all the other advantages of the original preparation.

SUMMARY AND CONCLUSIONS

1. A new preparation of penicillin incorporated in peanut oil and beeswax has been studied to determine its rate of absorption and its therapeutic efficacy.

2. The intramuscular injection of 1 c.c. containing 300,000 units of penicillin resulted in assayable concentrations of penicillin in the serum for twelve hours in 85 per cent of the patients studied, with measurable concentrations persisting for as long as twenty-one hours in 25 per cent. Following an intramuscular injection of 2 c.c. containing 600,000 units, detectable concentrations were found in 90 per cent of the subjects at twelve hours and in one-third of the patients for twenty-four hours. An injection of 600,000 units subcutaneously resulted in detectable concentrations of penicillin in the blood for twenty-four hours in all but one of the subjects studied.

3. Twenty-seven patients suffering from various infections were treated with doses varying from 300,000 to 600,000 units once or twice per day. The results were similar to those obtained with the use of other preparations of penicillin in beeswax and oil or with equivalent *per diem* doses of penicillin in aqueous solution.

4. The preparation used by us was found to be easier to administer than the preparations made according to the original Romansky formula.

We wish to thank Dr. William W. Zeller, for his assistance in the completion of these studies, and Miss Joan Rowe, for technical assistance.

PHARMACODYNAMIC EFFECT IN MAN OF STREPTOMYCIN CONTAINING A HISTAMINE-LIKE FACTOR

WILLIAM L. HEWITT, M.D., AND JOHN J. CURRY, M.D.
BOSTON, MASS.

IN A systematic study of the pharmacodynamic effects of streptomycin in animals, it has been demonstrated that the reactions to the pure compound differ from those of preparations which contain impurities.¹ Administration to man of streptomycin containing these impurities has resulted in severe reactions and in two instances death has occurred.² Solutions containing one of these contaminants produce a sudden fall in arterial blood pressure, peripheral vasodilatation, and inhibition of water diuresis when injected into rabbits. However, when the solutions are incubated with histaminase prior to injection, these reactions do not occur.³ Therefore, it has been considered generally that the impurity is histamine. Herein are presented additional data concerning the pharmacodynamic effects of this impurity of streptomycin solutions in man. For convenience, streptomycin solutions containing the histamine-like contaminating substance will be designated H-streptomycin and regular commercial streptomycin will be designated C-streptomycin.*

MATERIALS AND METHODS

Young adults who were in the terminal phases of penicillin therapy for primary and secondary syphilis but who were otherwise in good health and gave no personal or familial history of allergic disorder were used as subjects. H-streptomycin was dissolved in sterile distilled water in concentration of 100 mg. per cubic centimeter for intramuscular administration and further diluted to 5 mg. per cubic centimeter in physiologic saline for intravenous use. Control observations were made using C-streptomycin prepared for administration in a similar manner. Benadryl was dissolved in physiologic saline in a concentration of 30 mg. per 50 c.c. for intravenous use.

H-streptomycin was then injected intramuscularly in 100 to 500 mg. doses and intravenously in 50 mg. doses, and observations were made with special attention to peripheral vasodilatation, blood pressure, pulse rate, headache, and palpitation. The effectiveness of benadryl, a potent antihistamine substance, in altering these reactions was next observed by administering a dose of 10 mg. of benadryl intravenously five to seven minutes prior to the intramuscular injection of 500 mg. of H-streptomycin. In other subjects a dose of 10 mg.

This work was supported in part by a grant from The Upjohn Company, Kalamazoo, Mich.

Received for publication, Nov. 1, 1946.

*We are indebted to E. R. Squibb & Sons, New Brunswick, N. J., for supplying both lots of streptomycin. Manufacturers' tests and Food and Drug Administration regulations now prevent lots of streptomycin containing the histamine-like factor from reaching commercial channels.

of benadryl was given intravenously one minute after the intravenous injection of 50 mg. of H-streptomycin was begun and when the histamine-like reaction to it was well established. Comparatively small doses of benadryl were used because our supply of the drug was limited.

The effect of H-streptomycin on the gastric secretion was studied in nine subjects by analysis of the volume and free and total acidity of the gastric contents prior to and after the intramuscular injection of 500 mg. of H-streptomycin.

In two asthmatic subjects the effect of 50 mg. of H-streptomycin on the vital capacity was studied by methods previously described.^{4,5} Control observations were made using histamine base and C-streptomycin. The effectiveness of benadryl in preventing the reduction in the vital capacity which followed the injection of H-streptomycin and histamine base was then determined.

RESULTS AND COMMENT

Intravenous administration of 50 mg. of H-streptomycin produced a characteristic response in all of twenty patients tested. This consisted of a sensation of facial or generalized warmth, palpitation, throbbing headache, and objective evidence of peripheral vasodilatation by observation of facial suffusion. No notable alteration occurred in the pulse rate, respiration, or blood pressure, as determined by the usual clinical methods. Intramuscular administration of doses up to 500 mg., however, produced these changes in only 48 per cent of twenty-three individuals tested with the largest dose, 500 mg., and the reactions when present were frequently less severe than following intravenous administration of the drug (Table I). In seven subjects, when the intravenous administration of H-streptomycin was initiated and the characteristic response was evident, 10 mg. of benadryl were injected intravenously in the opposite arm. A prompt and marked amelioration of symptoms followed, and rapid blanching of the facial suffusion was noted despite the continued administration of the remainder of the 50 mg. dose of H-streptomycin. A dose of 10 mg. of benadryl was given intravenously to six subjects who previously showed sensitivity to intramuscular H-streptomycin, and five to seven minutes later the intramuscular administration of 500 mg. of H-streptomycin failed to produce the characteristic response.

A stimulating effect of H-streptomycin on the gastric secretion which closely resembles a histamine response is shown in Table II. A significant increase in free acidity and an increased total volume occurred in at least seven of the nine subjects studied.

In two asthmatic subjects it was previously shown that a quantitatively similar decrease in vital capacity followed the intravenous injection of identical amounts of histamine. Therefore, in Subject B. R., after a control injection of 50 mg. of C-streptomycin administered intravenously had produced no notable effect, a dose of 50 mg. of H-streptomycin was given by the same route, and vital capacities were recorded at intervals. The reduction in vital capacity that followed was similar to the reduction produced by the intravenous administration of 0.01 mg. histamine base. The protection afforded

by 30 mg. of benadryl given intravenously against the reduction in vital capacity produced by 50 mg. of H-streptomycin and 0.01 mg. of histamine base likewise was similar. However, when 4 mg. of acetyl- β -methylcholine chloride was injected intramuscularly thirty-four minutes after the benadryl was given, a pronounced decrease in vital capacity occurred, and epinephrine was necessary to afford relief from the induced asthmatic-like attack (Fig. 1).

In Subject J. D., after administration of 50 mg. of C-streptomycin had produced no notable effect, 50 mg. of H-streptomycin were injected intravenously, and the vital capacity was recorded at intervals. The reduction in vital capacity that followed was similar to the reaction due to the intravenous injection of 0.02 mg. of histamine base. As in the previous case, 30 mg. of benadryl administered intravenously afforded a similar protection against the reduction in vital capacity due to 50 mg. of H-streptomycin and 0.02 mg. of histamine given by vein. The reduction in vital capacity that followed the intramuscular injection of 1.0 mg. of acetyl- β -methylcholine chloride was not affected by the administration of benadryl (Fig. 2). In these two asthmatic subjects the reaction of the tracheobronchial tree to H-streptomycin and to histamine was similar. The protection afforded by 30 mg. of benadryl against H-streptomycin and histamine was likewise similar. The failure of benadryl in the dosage used to protect against the reduction in vital capacity due to acetyl- β -methylcholine chloride appears to indicate that the streptomycin contaminant is not related to acetyl- β -methylcholine chloride. Since it has been shown previously that under certain circumstances quantitatively similar amounts of bronchoconstriction can be produced by identical amounts of histamine, it may be possible to determine quantitatively the amount of histamine-like contaminant present in streptomycin solutions by this method.

Fig. 1.

Fig. 2.

SUMMARY

1. Throbbing headache, palpitation, and peripheral vasodilatation were observed uniformly in twenty young adult subjects following the intravenous administration of 50 mg. of streptomycin containing a histamine-like factor, but a similar histamine-like reaction was observed in only 48 per cent of twenty-three subjects following intramuscular administration of 500 mg. of the same material.

2. Small doses of benadryl given intravenously were effective in ameliorating these reactions to H-streptomycin.

3. In nine fasting young adult subjects, 500 mg. of streptomycin containing a histamine-like factor, administered intramuscularly, produced a significant increase in total volume of gastric secretion and the amount of free acid present.

4. In one asthmatic subject the intravenous administration of 50 mg. of H-streptomycin and 0.01 mg. of histamine base produced a similar degree of reduction in the vital capacity which was almost completely prevented by 30 mg. of benadryl given intravenously. In another subject essentially similar results were achieved when 0.02 mg. of histamine base was administered. Benadryl in the dosage used afforded no notable protection against the reduction in vital capacity due to acetyl- β -methylcholine chloride.

5. These studies in man furnish further evidence that one of the contaminating substances of impure solutions of streptomycin is histamine.

HISTAMINE ANTAGONISTS

VI. COMPARATIVE ANTIHISTAMINIC ACTIVITY OF SOME ETHYLENEDIAMINE DRUGS IN THE GUINEA PIG

SIDNEY FRIEDLAENDER, M.D., DETROIT, MICH., AND SAMUEL M. FEINBERG, M.D.,
AND ALAN R. FEINBERG, M.D., CHICAGO, ILL.

RAPID progress in the field of histamine antagonists has resulted in the development of several synthetic compounds which have proved successful to some degree in alleviating certain allergic manifestations in man. All of these substances are chemically and pharmacologically related. Among the first to be introduced in this country was benadryl, a benzhydryl ether of β -dimethylaminoethanol.¹ In France, *N'* phenyl-*N'* benzyl-*N*-dimethylethylenediamine (antergan) has been used clinically since 1942.² A search for more potent and less toxic compounds led to the development of two other substances, pyribenzamine³ and neoantergan.⁴ The former differs from antergan only by substitution of the pyridil for the phenyl ring, while neoantergan differs from pyribenzamine only by the addition of a methoxy group on the benzyl ring (Table I). A comparative study of the antihistaminic activity of these four compounds was undertaken, in order to serve as a basis for future studies in anaphylaxis.*

EXPERIMENTAL

The guinea pig responds to intravenous doses of histamine with characteristic bronchospasm and asphyxia difficult to distinguish from that observed in anaphylactic shock. The effect is rapid in onset, and death from fatal doses occurs within a few moments. Post-mortem examination reveals the characteristic pale emphysematous lungs in each instance. Unlike anaphylaxis, non-fatal histamine shock does not confer immunity to subsequent injections of histamine. In the present experiments the histamine was injected into the penile veins of adult male guinea pigs. The intracardiac route was avoided because of the possibility of fatalities from the direct action of histamine on the coronary circulation or other cardiac tissues.

From preliminary experiments⁵ we determined that 0.4 mg. per kilogram of histamine,[†] calculated in terms of the base, killed all control animals. Shock occurred in all guinea pigs from 0.3 mg. per kilogram but terminated fatally in only 50 per cent. All animals survived a dose of 0.1 mg. per kilogram of histamine. In order to determine as objectively as possible the degree of antihistaminic activity of each of these compounds, the amount of histamine neces-

sary to produce 100 per cent mortality in a group of guinea pigs receiving a standard dose of the drug was determined. In each instance the standard protective dose was 3 mg. per kilogram and was administered intraperitoneally fifteen minutes prior to the intravenous injection of histamine. It was previously determined that none of the solutions produced fatal toxic symptoms on intraperitoneal injection in doses below 50 mg. per kilogram. Animals surviving histamine shock were not used again for at least forty-eight hours.

RESULTS (TABLES II AND III)

In those animals protected with 3 mg. per kilogram of benadryl, the dose fatal to all controls (0.4 mg. per kilogram of intravenous histamine) produced only a 29 per cent mortality. Two milligrams per kilogram were necessary to kill all benadryl-protected animals. Antergan gave approximately the same amount of protection, 2.4 mg. per kilogram of histamine being required for the 100 per cent fatal dose in animals receiving this drug. Equivalent doses of pyribenzamine afforded more protection against histamine than either benadryl or antergan. The animals receiving pyribenzamine exhibited little evidence of shock from doses of histamine as high as 2.0 mg. per kilogram. The majority recovered from histamine shock produced by 10 mg. per kilogram, while a dose of 15.0 mg. per kilogram was found fatal for all guinea pigs in this group. Neoantergan, which is only slightly different in chemical structure from pyribenzamine, conferred even greater protection on some animals. While 10 mg. per kilogram of histamine produced approximately the same mortality in this group as in the pyribenzamine-protected guinea pigs, more than half of the neoantergan animals were able to survive doses of 25.0 mg. per kilogram. Fifty milligrams per kilogram of histamine were found to be the 100 per cent fatal dose in this group. On the basis of the number of lethal doses of histamine required to produce 100 per cent mortality in animals protected with a standard

dose of each drug, pyribenzamine would thus appear to be approximately 6 to 7 times more active than either benadryl or antergan, while neoantergan would possess almost 3.5 times the activity of pyribenzamine (Table IV).

DISCUSSION

The protective effect of these agents against the lethal effects of histamine is striking and indicates a great degree of specific antagonism. Various investigators have reported that these compounds also exert marked anti-

anaphylactic activity.^{2, 3, 5-7} This action together with the beneficial effects observed in certain allergic disorders is in accord with the theory that histamine plays an important role in anaphylaxis and allergy. In our own experiments we also found these drugs capable of modifying anaphylaxis in the guinea pig. Preliminary studies did not show a marked difference in the antianaphylactic activity of these compounds comparable to the variation exhibited in histamine shock. Further experiments are being carried out in order to clarify, if possible, this apparent discrepancy.

SUMMARY

A comparison was made of four antihistaminic substances, benadryl, pyribenzamine, antergan, and neoantergan. All compounds afforded some protection to guinea pigs against the fatal effects of intravenous histamine. Five to six times the LD 100 of histamine was necessary to kill all animals protected with 3 mg. per kilogram of benadryl or antergan. The same dose of pyribenzamine was able to protect some animals against as much as thirty-five lethal doses, while neoantergan protected some animals against as much as three times this amount of histamine.

UNUSUAL INSTANCES OF AURICULAR FLUTTER

S. F. ARONSON, M.D., AND L. N. KATZ, M.D.

CHICAGO, ILL.

THE finding of either 1:1 or persistent 3:1 A-V conduction in auricular flutter is so rare that their occurrence merits attention. Two case histories, each illustrating one of these mechanisms electrocardiographically, are presented.

CASE REPORTS

CASE 1.—The first case is that of a 42-year-old white man with a bronchogenic carcinoma and extensive metastases which caused almost complete obstruction of the esophagus. A gastrostomy was performed to relieve the effects of compression. The patient became progressively weaker during his hospital stay. On the evening of the forty-ninth postoperative day, the heart rate became rapid (160 beats per minute) and irregular with a pulse deficit. The rate continued to increase until it was too rapid to be accurately counted. The patient's body became covered by a cold and clammy perspiration, the skin developed a cadaveric hue, and loud bubbling râles could be heard throughout the chest. He lost consciousness and the blood pressure could not be obtained. Oxygen therapy was immediately instituted and an electrocardiogram was taken (Fig. 1). This showed a ventricular rate of 296 beats per minute. Deep pressure applied over the right and left carotid sinuses had no effect on the ventricular rate. About three hours after the onset of the rapid heart rate, 0.48 Gm. of quinidine was given intramuscularly with massage and heat over the injection site to aid in absorption. Ten minutes later, one of the house physicians in attendance noted that the heart rate counted at the apex was 148 beats per minute and regular, and "flutter waves" at twice this rate were visible in the neck veins. The patient regained consciousness and responded to questioning. The slower ventricular rate persisted until the patient's death, which occurred several hours later. The slowing of the heart rate so soon after the intramuscular injection of the quinidine naturally raises doubt that it was due to this drug. Unfortunately, an electrocardiogram demonstrating the change in the heart rate was not obtained, but because the slower rate was exactly one-half that of the faster one and because of the visible auricular waves in the neck veins at a rate of 296, it was felt that the mechanism had converted from auricular flutter with 1:1 conduction to one with 2:1 conduction.

Discussion.—Some authors¹⁻³ have referred to several of the difficulties which may be encountered in distinguishing auricular flutter from the paroxysmal tachycardias. However, the gradual onset of the arrhythmia, the extremely rapid and regular ventricular rate (296 beats per minute), the absence of electrical quiescence during the auricular cycles, the normal configuration of the QRS complexes, and the clinical observation of the halving of the ventricular rate from 296 to 148 beats per minute with flutter waves visible in the neck veins established the diagnosis of an auricular flutter with 1:1 conduction in this case.

From the Cardiovascular Department, Michael Reese Hospital.

Aided by the A. D. Nast Fund for Cardiovascular Research.

The department is supported in part by the Michael Reese Research Foundation.

Received for publication, Nov. 15, 1946.

The occurrence of transmission of every impulse to the ventricles is extremely rare in auricular flutter. In 1933, Bedell¹ was able to find only twenty-four such cases reported in adults. This is explained by the normally long absolute refractory phase in the A-V node which interferes with the transmission of the frequently recurring auricular impulses, which in auricular

Fig. 1.

flutter have a rate usually between 250 and 400 beats per minute. Only when some circumstance abbreviates the duration of the refractory phase of the A-V node can every impulse be transmitted. Abbreviation of the refractory phase of the A-V node may occur as a result of injury or during sympathetic

stimulation (excitement, adrenalin). Usually this occurs⁶ when the flutter rate is slower than 250 beats per minute. Such slowing of the auricular flutter rate is best exemplified by the exhibition of quinidine, whereby the auricular rate may even be slowed to below 200 impulses per minute.

Fig. 2.

The other unusual feature in this case is the fact that 1:1 conduction occurred with an auricular rate of almost 300 making the ventricular rate itself rapid. Such rapid ventricular rates are rare. In 1937, a survey of the literature by Lyon⁷ revealed seventeen reported cases with a ventricular rate of over 280 beats per minute. Of these seventeen cases twelve were accompanied by graphic evidence, and of these latter only four (including a 14-

year-old boy) were in adults. Edeiken,⁸ in 1943, reported the case of a 46-year-old woman in whom, twenty-two days after an acute myocardial infarction, paroxysms of tachycardia (either supraventricular or 1:1 auricular flutter) occurred with ventricular rates of 310 and 303 beats per minute. Ours is therefore another instance of ventricular tachycardia over 280 which was due to 1:1 auricular flutter.

CASE 2.—This 52-year-old colored woman entered the hospital because of orthopnea, dyspnea on exertion, and swelling of the ankles for the six months prior to admission. An electrocardiogram revealed auricular flutter with a 2:1 A-V conduction. With the institution of therapy, the patient improved clinically. Other electrocardiograms showed persistent flutter with 2:1 and 4:1 A-V conduction and occasional ventricular premature systoles, the auricular rate being about 300 beats per minute. The fourth record (Fig. 2) revealed the very rare phenomenon of auricular flutter with a regular ventricular rate and a persistent 3:1 A-V conduction. Several days after this last tracing, oral quinidine, 0.2 Gm. every two hours and a total dosage of 2.8 Gm., was given following an initial test dose. The auricular flutter persisted, so after a rest period of three days quinidine therapy was again instituted. Within a period of thirty hours the patient received a total of 6 Gm. of quinidine which was divided into three separate courses. Careful check was made for evidence of cinchonism; frequent cardioscopic examinations were made, and an electrocardiogram was taken between each course. Fig. 3A shows the conversion of the flutter mechanism to a sinus rhythm with bigeminy (ventricular premature systoles). The bigeminy may have been due, in part at least, to digitalis (0.2 mg. digitaline nativele daily) which the patient received throughout the period of quinidine administration. All medication was discontinued after the bigeminal rhythm was found, and an electrocardiogram taken forty-eight hours later showed a sinus rhythm with only an occasional ventricular premature systole (Fig. 3B).

Discussion.—Occasional cycles with 3:1 conduction in cases of auricular flutter with an irregular ventricular rate are not uncommon. However, the occurrence in auricular flutter of a persistent 3:1 conduction is extremely rare.^{6, 9} Thus, this case is the first one in which this phenomenon has been found in over 30,000 electrocardiograms taken at the Michael Reese Hospital. The very regular, saw-toothed flutter waves, occurring at a rate of 270 cycles per minute, are best seen in Leads II and III of Fig. 2. Closer inspection will disclose their presence in the other leads as well. We are aware of only three such previous cases on record.¹⁰⁻¹² It has been postulated that 2:1 A-V conduction in auricular flutter is due to a focal interference which prevents every second auricular impulse from stimulating the ventricles; 4:1 A-V conduction would occur if a second block existed which would allow only one-half of the impulse that had penetrated the first block from reaching the ventricles. This would readily explain the relative frequency of 2:1 A-V conduction and the less common occurrence of 4:1 A-V conduction. However, this theory cannot account for the existence of a persistent 3:1 A-V conduction. The presence, even on occasion, of persistent 3:1 conduction indicates either that the hypothesis previously stated is erroneous or that a single region of interference may become so protracted as to allow the penetration of only one out of every three beats.

Another interesting feature in this case is the establishment of a bigeminal rhythm after the flutter mechanism was broken (Fig. 3A). Finally, in Fig. 3B

is illustrated the quinidine effect on the electrocardiogram with marked T-wave inversions (except in Lead III) and the prolongation of electrical systole (0.40 second; normal, 0.29 to 0.37 second).

A

B

Fig. 3.

SUMMARY

1. A very rare instance of auricular flutter with a 1:1 conduction and a ventricular rate of 296 beats per minute is presented.

2. An even rarer phenomenon is shown, namely, a case of auricular flutter with a persistent 3:1 A-V conduction.

EFFECT OF OXYGEN ON MALARIA

AN IN VIVO STUDY IN DUCKS

R. H. RIGDON AND NONA B. VARNADOE

LITTLE ROCK, ARK.

PATHOLOGIC studies on a child dying from a *Plasmodium falciparum* infection,¹ on monkeys dying from *Plasmodium knowlsi* infection,² and on ducks dying from *Plasmodium lophurae* infection³ showed lesions that were similar to those occurring in shock. It was suggested that they resulted from anoxemia. This anoxemia resulted from the anemia produced by the rapid destruction of red blood cells by the plasmodia. Subsequent studies have shown that the blood of ducks with a severe malarial infection at the time of death may have only 15 to 20 per cent of the normal blood oxygen carrying capacity.⁴ Anoxemia in malaria is again manifest when ducks with malaria are placed in a decompression chamber in that they succumb before the non-infected birds. The length of survival in these malaria-infected ducks, when in the presence of decreasing amounts of oxygen, may be correlated with the degree of parasitemia.

The clinical observations of Kean and associates^{5, 6} support the role that shock may play in acute malarial infections in man. They presented six cases in support of the opinion that medical shock may develop in patients with algid malaria. In three of their cases there was "hemoconcentration, evidence of an increase in the hematocrits, red blood cell count, and hemoglobin. The blood pressure was lowered and there were other signs of vasomotor collapse. . . . The final evidence for shock in these cases was the response to replacement therapy. Plasma was used in three cases, whole blood transfusion in one, oxygen in two, 'Eschatin' in two, intravenous fluids in five, and epinephrine in five."

Ducks with a severe malarial infection show clinical improvement immediately when given a transfusion of duck blood.⁷ The red blood cells replace those destroyed by the parasites; thereby more oxygen can be transferred to the tissue. A study has been made to determine the effect of increasing the amount of oxygen available to ducks to see the effect upon the course of the disease. The results of this study are reported at this time.

METHODS AND MATERIAL

White Pekin ducks 2 to 4 weeks of age were used. Blood from donor birds infected with *P. lophurae* was used to infect the ducks. In each experiment a group of birds from the same hatching were inoculated intravenously with blood from the same donor bird.

From the Department of Pathology, School of Medicine, University of Arkansas.

Research paper No. 598, Journal Series, University of Arkansas.

This work was aided by a grant from the John and Mary R. Markle Foundation.

The oxygen was supplied by the Linde Air Products Company and the anticoagulant Li-quaemin by Roche Organon, Incorporated.

Received for publication, Oct. 9, 1946.

The course of the infection was followed by counting the number of parasitized cells per 500 red blood cells. Blood films were stained with a combination of Giemsa's and Wright's stains.

Total red blood cell counts were made on some of the ducks. Haymen's fluid was used as the diluent. Hematoerit readings were obtained by centrifuging 10.0 c.c. of heparinized blood for thirty minutes in Wintrobe tubes. Liquemiu was the anticoagulant and was used in a dilution of 1 to 9.

The oxygen chamber was 60 by 32 by 24 inches in size. It was made from galvanized iron supported by an angle iron frame. The bottom had a 2 inch drop from one end to the other. The top of the chamber was made of glass. The door was located at one end of the chamber. A wire meshed floor was placed 3 inches from the bottom. A 2 inch pipe was put in the bottom of the chamber at its lowest point. Water was run continuously into a container used for the ducks to drink from, while the overflow ran over the bottom of the chamber and out into a floor drain. Two small holes were made through the top of the chamber. A thermometer was kept in one and samples of oxygen were removed through the other.

A tank of oxygen was placed adjacent to one end of the chamber. A regulator was used to control the flow of oxygen. The rubber tube carrying the oxygen entered the chamber through a hole in the top. The concentration of oxygen within the chamber was determined frequently with an oxylizer.* The concentration of oxygen varied during the experiments; usually it was kept at a concentration of 50 to 60 per cent during the first few days of the disease and then increased to 80 to 90 per cent. In some experiments the birds were kept continuously within the oxygen chamber for days, while in others they were removed daily for short intervals to obtain blood for the tests. Samples for hematoerit determination were obtained by cardiac puncture, and the birds were discarded thereafter. Blood for cell counts and films were obtained by puncturing a vessel in either the leg or web of the foot.

EXPERIMENTAL

Variations in Erythrocyte Count of Normal Ducks Kept in Oxygen Chamber.—Six young ducks were kept in the oxygen chamber for two weeks with a 50 to 70 per cent concentration of oxygen. The average red blood cell count in these birds is shown in Fig. 1. During the first five days there was a diminution in the total number of red cells, after which the number rapidly returned to normal levels. The erythrocyte count remained within the range of normal during the twelve subsequent days during which the birds were kept in the oxygen chamber. There was no variation in the red cell count for six days after the ducks were removed from the oxygen chamber.

Effect of Oxygen on Parasitemia in Ducks Infected With P. lophurae.—Twenty ducks 15 days of age were inoculated with malaria and ten were put into the chamber with a concentration of 50 per cent oxygen. The parasitemia was followed in five birds in the oxygen chamber and in five of the group kept in the duck room. The average degree of parasitemia in these two groups of ducks is shown in Fig. 2. The parasitemia is the same in the two groups until the fourth day following which time there is an increase in the number of parasites in the oxygen-treated group when compared with those kept in the duck room. By the sixth day of the disease, eight of the ten ducks with malaria kept in the duck room were dead, while only five of the ten ducks

*The Ohio Chemical & Mfg. Company, Cleveland, Ohio.

with malaria kept in the oxygen chamber were dead. The concentration of oxygen was increased to approximately 75 to 80 per cent on the morning of the sixth day as shown in Fig. 2. The remaining five ducks in the oxygen chamber survived until the morning of the seventh day. These five ducks died within seven minutes following the time they were removed from the oxygen chamber.

Fig. 1.—Changes which occur in the number of red cells in normal ducks kept in an oxygen chamber.

Fig. 2.—The average degree of parasitemia in five ducks kept in the oxygen chamber and of five ducks kept in normal atmosphere. The concentration of oxygen is indicated on the graph.

TABLE I

EXPERIMENTAL DAY	OXYGEN CHAMBER	CONTROLS KEPT IN DUCK ROOM
1	4.1	3.0
2	9.4	8.0
3	16.7	15.6
5 (A.M.)	285.3	127.9
5 (P.M.)	290.0	126.0
6 (A.M.)	325.0	158.0
6 (P.M.)	300.0	137.9
7 (A.M.)	129.0	59.3
7 (P.M.)	95.0	26.0

The effect of oxygen on the parasitemia in ducks was determined in a second experiment in which forty-one birds 16 days of age were used. Twenty of these were put into the oxygen chamber on the fourth day following inoculation. The concentration of oxygen was kept at approximately 50 per cent for twenty-four hours, after which time it was increased to 85 to 90 per cent for the following two days when the experiment was discontinued. The average parasitemia of twenty of these birds was 286 parasitized cells per 500 red blood cells on the fourth day, at the time that the twenty ducks were put into the oxygen chamber. The average parasitemia of ten of these ducks in

Fig. 3.—The red cell counts, the hematocrit readings, and the parasitemia as observed in ducks infected with *P. lophurae* kept in the oxygen chamber. Two malaria-infected ducks were used to establish each point, except on the sixth day when five birds were used. One normal duck was used to establish the daily values for the controls. A progressive anemia occurred in the malaria-infected birds, while a temporary anemia occurred in the noninfected birds kept under the same environmental conditions.

the oxygen chamber after eighteen hours was 420 parasitized cells per 500 red blood cells, while the average of twenty control ducks was 340 cells. At 9:45 A.M. on the sixth day, eighteen ducks were dead from the group of twenty-one given malaria and kept in the duck room, while only eleven birds were dead from the group of twenty given malaria and put in the oxygen chamber. One of the group removed from the oxygen chamber died about five minutes later.

In a third experiment, twenty ducks 18 days of age were inoculated and ten were put immediately into the chamber with a 50 per cent concentration of oxygen and kept there until the fifth day, at which time the concentration of oxygen was increased to approximately 80 to 85 per cent. The experiment was discontinued on the afternoon of the seventh day. At this time five ducks were dead from the group of ten inoculated with malaria and put in the oxygen chamber, while only one was dead from the group of ten kept as controls in the duck room. The average degrees of parasitemia per 500 erythrocytes in these two groups of ducks are given in Table I.

Fig. 4.—The experiment as shown in Fig. 3 was repeated with the ducks kept in the room rather than being put into the oxygen chamber. The parasitemia is much less in this group of birds than in those kept in the oxygen chamber. The anemia and the hematocrit readings are similar to those shown in Fig. 3.

The degree of parasitemia is much greater in the group kept in the oxygen chamber than it is in the control group. The peak of parasitemia apparently was reached at approximately the same time in the two groups. It is not surprising to find a larger number of birds dying in the oxygen-treated group than in the control group, since the parasitemia was much higher in the oxygen-treated group of ducks.

The red blood cell count, the hematocrit readings, and the degree of parasitemia were followed in two groups of ducks, one of which was kept within the oxygen chamber for the entire experiment and the second in batteries in the duck room. A total of forty-four ducks 16 days of age were used. The previously mentioned observations were made upon a different bird each day after which it was discarded. The concentration of oxygen within the chamber, the red blood cell count, the hematocrit reading, and the degree of parasitemia are shown in Fig. 3. The results of similar observations on the control group are shown in Fig. 4. The peak of parasitemia was reached on the fifth day in both groups of ducks; however, the parasitemia was much higher in those kept in the oxygen chamber than it was in the control group. A progressive decrease occurred in the number of red cells and in the hematocrit readings in all ducks regardless of whether they were in the control group or in the oxygen chamber. The red blood cell counts and the hematocrit readings of nonmalarial birds kept in the oxygen chamber with the infected birds decreased during the first four days following which time they rapidly increased to within the range of normal (Fig. 3). Normal ducks used for the controls did not show any significant variation in the red cell count and hematocrit reading during a corresponding interval as shown in Fig. 4.

CLINICAL EFFECT OF OXYGEN ON DUCKS WITH MALARIA

Normal ducks kept in the chamber in the presence of 50 to 60 per cent concentration of oxygen showed no clinical symptoms different from those of normal birds kept in the batteries in the duck room. Ducks inoculated with *P. lophurae* and put immediately in the oxygen chamber progressively became pale and weak and ultimately succumbed in a manner identical with that of the ducks with malaria kept in the duck room. However, ducks with a high degree of parasitemia, an anemia, weakness, and a rapid respiratory rate, when put into the chamber with a 50 to 60 per cent concentration of oxygen, immediately showed an increase in activity, and the respirations decreased in frequency and apparently became deeper. The ducks looked markedly improved almost immediately.

There is little difference in the time that death occurs in groups of ducks put into the oxygen chamber immediately following inoculation when compared with the controls kept in the batteries in the duck room. There is, however, a definite increase in the length of survival of malaria-infected birds put into the oxygen chamber on the fourth day of the disease as compared with a similar group kept only in the duck room as shown in Fig. 5.

In this experiment, twenty-five ducks 16 days of age were inoculated with malaria. On the fourth day at 10:00 A.M. the average parasitemia in ten of these ducks was 298 parasitized cells per 500 red blood cells, and in the afternoon it was 304. Ten of the group of twenty-five ducks were put into the oxygen chamber at 4:00 P.M. on the fourth day of the disease. These ducks were carefully watched during the following forty-eight hours to determine the time of death. The oxygen chamber was kept closed during this time. The

time of death and the concentration of oxygen within the chamber are shown in Fig. 5. At 11:30 A.M. on the sixth day, eight of the ten ducks in the oxygen chamber were dead, while twelve of the 15 birds with malaria kept outside of the chamber were dead. Thirty-five minutes following the time of removal of the chamber, one died; the second survived for twenty-four hours after removal. It is obvious from Fig. 5 that ducks with a high degree of parasitemia survive for a much longer time when put into a chamber with a high concentration of oxygen than similarly infected ducks kept at normal atmospheric pressure.

Fig. 5.—The time at which death occurred in the oxygen-treated birds and the controls is indicated here. The concentration of oxygen in the chamber is shown in this figure.

DISCUSSION

The experimental observations as made in these studies indicate that oxygen is beneficial to ducks with a severe malarial infection. The increased amount of oxygen apparently helps to compensate for the decrease in the amount of hemoglobin which is present in the highly infected birds. The anemia results from the rapid destruction of red cells by the plasmodia. In *P. falciparum* infections in man the total decrease in the number of red cells may not be so great in some cases; however, the important factor in all types of acute malaria seems to be the rapidity in which the anemia may develop. The fact that ducks with a severe malarial infection show immediate improvement, either following a transfusion with duck red cells or when they are put in the presence of an increased concentration of oxygen, would suggest that clinical sub-

jects with acute malaria and symptoms of shock should be given a transfusion and placed in an oxygen chamber at the same time that a plasmodial drug is given.

The fact that ducks with a *P. lophurae* infection show a higher degree of parasitemia when kept for the entire period of the disease in the presence of an increased concentration of oxygen does not contradict the beneficial effects that may result from the use of oxygen, since it has been shown experimentally that ducks with a severe infection when placed in the oxygen chamber show immediate clinical improvement. An interval of a few hours is important in the treatment of acute malaria, since it requires such a time for the effects of the plasmodial drugs to manifest themselves upon the parasites, and during this interval the patient may need supportive therapy for the anoxemia. It of course would be useless to kill the plasmodia and permit the patient to die from medical shock. As far as it is known there are no contradictions to the use of transfusions and oxygen in the treatment of a patient with malaria.

Cullen and Boothby and their associates^{6, 9} have given the indications and rationale of oxygen therapy. Cullen and associates have emphasized the fact "that there is a $5\frac{1}{2}$ to $7\frac{1}{2}$ per cent increase in metabolism for every degree (Fahrenheit) of elevation in temperature; it would seem logical to provide these individuals with oxygen in excess of that present in the atmosphere."⁸ Patients with acute malaria, therefore, would be benefited by oxygen if they had only an increase in their metabolic rate as a result of the fever. Alkalosis present during fever furthermore effects a significant reduction in the arterial oxygen tension even in the presence of a normal arterial oxygen saturation.⁸ "The administration of oxygen benefits the patient chiefly by physical methods. That is, an increase in the alveolar concentration increases the partial pressure, thereby increasing the saturation of the blood with a consequent increase in tension in spite of the elevated pH. The break in the vicious cycle of low tension, high pH, and tissue hypoxia may also be effected by the increased amount of oxygen in physical solution in the plasma, which oxygen is readily available to the tissue and not dependent on dissociation of hemoglobin."⁸

Experimental and clinical studies indicate that shock may occur in severe malarial infections.^{1, 2, 6} In the treatment of shock from any cause, all efforts should be directed to improve the circulation of blood through the tissue so that oxygen can be delivered at a higher partial pressure. Administration of 100 per cent oxygen is the most direct and specific method to increase the oxygen pressure in the capillaries and tissue fluids.⁹ A 100 per cent concentration of oxygen has been administered to patients for forty-eight hours without any evidence of pulmonary irritation.⁹

There is nothing in these experimental studies to indicate that oxygen per se will cure malaria. In fact, these studies show that the parasitemia in *P. lophurae* infection in ducks kept in the presence of a high concentration of oxygen is higher than that which occurs in ducks kept in the presence of the concentration of oxygen as occurs in the normal atmosphere. Experimental studies have indicated that the sudden decrease in the degree of parasitemia which occurs following the peak of parasitemia in *P. lophurae* infec-

tion in ducks may be the result of a lack of oxygen which apparently is essential for the survival and multiplication of these plasmodia in vivo.¹⁰

The clinical improvement, as observed in ducks with a severe malarial infection when given oxygen, supports the opinion that anoxemia is a significant factor in the mechanism of death in malaria. All of our physiologic and pathologic studies have shown the effects of a lack of oxygen in malaria,^{1-4, 11} and now the results from the use of oxygen and the results following transfusions show the therapeutic effects which may be accomplished in the treatment of acute malaria as suggested from these studies in the duck.

SUMMARY

Ducks with a severe malarial infection when placed in an oxygen chamber immediately show marked clinical improvement. They survive for ten to eighteen hours longer than similarly infected ducks kept in the duck room. This improvement is attributed to the greater amount of oxygen available for transmission to the anoxic tissues.

The use of oxygen in the treatment of acute malarial infections in man is discussed.

DETERMINATION OF NORMAL MEAN CORPUSCULAR WEIGHT (ERYTHROCYTE)

CHEN-TING CH'IN, M.B., CH.B.
New York, N. Y.

OUR knowledge in various types of anemia has been put on a much more sound basis since the discovery of methods of determining and interpreting the mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration of red cells. It occurred to me that additional help might be derived from the estimation of the mean corpuscular weight of the erythrocyte. This determination was carried out in eighty-one normal subjects including ten Chinese and seventy-one Filipinos. The determination was performed according to the same principles used for the mean corpuscular volume, employing the Wintrobe tube.

METHOD AND RESULTS

All the subjects studied were medical students and doctors of normal development and nutritional status. The erythrocyte count, hemoglobin, leucocyte count, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration were found to be within normal limits in each instance. The determination of mean corpuscular weight was made from the same sample of blood.

The capacity of several standard Wintrobe tubes was accurately determined by weighing, on an analytic balance, tubes emptied and filled with distilled water. The capacity of each tube used in these measurements was known to the nearest tenth of a milligram. For simplicity in presentation of the data, a uniform capacity of 0.7 c.c. between the 0 and 100 mm. marks is assumed; in the actual calculations the capacity of each individual tube was used. The technique of the determination was as follows.

The weight of a standard Wintrobe tube was carefully measured. The tube was filled with blood exactly to the 100 mm. mark and centrifuged for at least thirty minutes at 3,000 revolutions per minute. After the hematocrit reading had been taken, the supernatant plasma was removed by capillary pipette without disturbing the cellular sediment. In doing so a column of plasma, platelets, and leucocytes, a few millimeters in length, was left on top of the red blood cells. The tube containing the packed red blood cells and a small amount of plasma was then weighed. When the weight of the empty tube was subtracted from this weight, the weight of the cells and the residual plasma was obtained. The weight of 1 c.c. of plasma made from the same blood sample was measured with a separate set of glassware. From the latter the weight of 0.7 c.c. of plasma was calculated. Dividing the weight of the 0.7 c.c. of plasma by 100, we obtained the weight of a 1 mm. column of the plasma in the Wintrobe tube. By assuming that the density of leucocytes and platelets is equal to that of plasma, and by application of a suitable coefficient to the measured length of the plasma remaining in the tube, we could determine

the weight of the residual material. The weight of the blood cells in 1 c.c. of whole blood was derived as follows.

If it is assumed that the tube is of uniform bore, then:

$$\text{Weight of blood cells in 1 c.c. of whole blood in mg.} = \frac{\text{Weight of Wintrobe tube containing the packed cells and residual plasma} - \text{Weight of tube and weight of residual plasma}}{0.7}$$

$$\text{Weight of cells of 1 c.mm. in mg.} = \frac{\text{Weight of blood cells/c.c.}}{1,000}$$

$$\text{Weight of cells of 1 c.m. in } \mu\text{Gm.} = \frac{\text{Weight of cells/cc.}}{1,000} \times 1,000,000,000$$

$$\text{M.C.W.*} = \frac{\frac{\text{Weight of cells/c.c.}}{1,000} \times 1,000,000,000}{\text{R.B.C./c.mm. in million} \times 1,000,000}$$

$$\text{M.C.W.} = \frac{\text{Weight of cells/c.c. in mg.}}{\text{R.B.C./c.mm. in million}} \text{ micromicrograms}$$

Fig. 1.—Distribution of mean corpuscular weight of thirty-eight men, ●, and forty-three women, ○ (μGm.).

The mean corpuscular weights of the eighty-one subjects are presented in Fig. 1. It is significant that in thirty-four of the thirty-eight men and in thirty-five of the forty-three women, the mean corpuscular weight falls within the range of 90 to 110 micromicrograms. The figures for the entire series calculated according to standard statistical methods are shown in Table I. The general hematologic data of the series are shown in Table II.

TABLE I. MEAN CORPUSCULAR WEIGHT (μGm.) IN EIGHTY-ONE NORMAL SUBJECTS

	NUMBER OF CASES	MEAN $\pm \frac{\sigma}{\sqrt{N}}$	S. D. $\pm \frac{\sigma}{\sqrt{2N}}$
Men	38	96.9 \pm 1.04	6.43 \pm 0.74
Women	43	96.6 \pm 1.29	7.47 \pm 0.81
Whole series	81	96.8 \pm 0.78	7.02 \pm 0.55

*M. C. W., mean corpuscular weight.

TABLE II. HEMATOLOGIC DATA OF EIGHTY-ONE NORMAL SUBJECTS (TEN CHINESE AND SEVENTY-ONE FILIPINOS)

	PRESENT SERIES		FILIPINO STANDARD		AMERICAN STANDARD	
	MEN (38 CASES)	WOMEN (43 CASES)	MEN	WOMEN	MEN	WOMEN
R.B.C. (million)	5.26 (4.24-5.91)	4.74 (4.19-5.35)	5.1 (4.2-5.5)	4.5 (4.0-5.0)	(4.8-6.5)	(4.3-5.5)

Mean corpuscular hemoglobin	27.0 (26-29)	27.4 (26-30)	27 (22-34)	27 (22-34)	(26.5-31.5)	
Mean corpuscular hemoglobin concentration	30.5 (28-34)	31.4 (29-35)	27 (23-32)	27 (23-32)	(33-39)	
Mean corpuscular weight	96.9	96.6				

DISCUSSION

The author has no knowledge that the mean corpuscular weight of erythrocytes has been studied previously. Without clinical application in pathologic conditions it is difficult to evaluate the significance of this determination. However, it is reasonable to assume that the mean corpuscular weight should be increased (hyperponderal) in macrocytic hyperchromic anemia and should be reduced (hypoponderal) in microcytic hypochromic anemia. In such conditions the determination of the mean corpuscular weight might serve as a collaborative method in differential diagnosis.

With known methods of study changes of the erythrocyte, other than changes of size, shape, and hemoglobin content, cannot be determined. In this respect the mean corpuscular weight might give additional information, not only in the study of anemia but also in other conditions causing disturbance of fluid and salt balance. However, this is something for future study to prove.

SUMMARY

1. A method of determining the mean corpuscular weight of erythrocytes is presented.

2. The mean corpuscular weight was found to be $96.9 \mu\mu\text{Gm.}$ (S. D. = 6.43) for thirty-eight normal men and $96.6 \mu\mu\text{Gm.}$ (S. D. = 7.74) for forty-three women, with an average of $96.8 \mu\mu\text{Gm.}$ (S. D. = 7.02) for both sexes.

3. The application and significance of this determination are to be ascertained by future study in pathologic conditions.

This study was made in the laboratories of the Cancer Institute of the University of the Philippines, Manila, when the author was stranded there by the Pacific War in 1944. The author wishes to express her gratitude to the members of the laboratories for this privilege and also to Dr. Eugene Stransky of the Philippine General Hospital.

THE BONE MARROW OF NORMAL CATS

ARTHUR SAWITSKY, M.D.,* AND LEO M. MEYER, M.D.
NEW YORK, N. Y.

INTRODUCTION

SINCE Arinkin's¹ original description of sternal marrow aspiration in human beings, the method has been applied to dogs by Alexandrov.² Meyer and Bloom³ studied normal canine bone marrow obtained by aspiration of the iliac crest, utilizing the technique of Ito and associates⁴ who were concerned with investigations in leishmaniasis. Lawrence and co-workers⁵ refer to the normal bone marrow of the cat in their paper on feline agranulocytosis. These investigators studied histopathologic sections of bones which were fixed in Zenker's fluid, embedded, and cut. They also examined films made from marrow taken from the humerus and femur which were macerated in human serum and stained with Wright's fluid. This method permitted little opportunity for repeated examinations, and the maximal number of observations made on any animal was three. The majority of animals were sacrificed before they were studied. The procedure to be introduced overcomes this disadvantage because of its simplicity of performance and the availability of the same animal for innumerable punctures. In presenting the data we also compare our observations on the peripheral blood with those of other investigators.

MATERIAL AND METHODS

Studies were made on fifteen apparently normal laboratory cats, both male and female, of unknown age and ranging in weight from 1.69 to 3.43 kilograms each. In the cat the innominate bones articulate with the sacrum and extend caudoventrally, turning medially to unite in the midline to form the symphysis. The ilium extends from the sacrum to the acetabulum. It is contracted in its mid portion and broader at the periphery. The proximal end is thickened, forming the crest, and runs roughly parallel to the vertebral column.

The technique for marrow puncture is as follows: The animal is strapped to the table with dorsum presenting and extremities extended. The hair over the sacral area is clipped and the skin sterilized with any suitable antiseptic. Local anesthesia is not required. The anterior-superior border of the iliac crest is outlined with the fingers of one hand. A sterile 18 to 19 gauge spinal tap needle with straight stylet, about 1½ inches long, is inserted through skin and muscle close to the iliac crest. Upon reaching the periosteum the needle is simultaneously rotated and pushed with a dextro-levo boring movement until the medullary cavity is entered. The marrow cavity has been entered when the needle seems firmly imbedded in the bone and only rarely is a sudden "give" experienced. The stylet is removed, a dry 20 c.c. syringe is attached to the needle, and about 0.1 or 0.2 c.c. of marrow is aspirated. The needle, together with the attached syringe, is then removed from the animal and the drop expelled on a clean glass slide. From the drop white cell and megakaryocyte counts are made with the same technique as for counting peripheral blood. Thin films are made

*Fellow in Hematology.

on several clean glass slides and stained with Wright's stain. Five hundred nucleated cells are counted and the percentages estimated for the differential count from the stained films, utilizing the classification of Vogel and associates.⁶ In Fig. 1 is shown the aspiration needle in the iliac crest.

Fig. 1.—Aspirating needle in position in the iliac crest.

OBSERVATIONS

A comparison of the data obtained in the peripheral blood (Table I) with those of other observers (Table II) shows a similarity of results which indicates that the animals utilized in the present study were apparently normal. The only exception is Cat 672 in which the leucocyte count was 40,500 per cubic millimeter. The animal appeared to be well.

The bone marrow from the iliac crest (Table III) shows an increased number of nucleated cells and megakaryocytes as compared with that of human beings and dogs (Table V). The myeloid series constitutes 69.9 per cent of the nucleated cells which are distributed mainly among the segmented (22.5 per cent) and nonsegmented (30.5 per cent) neutrophils. The metamyelocytes constitute only about 13 per cent of the total number. This increased cellularity of the bone marrow with maturation of cells of the myeloid series is apparently specific for the cat, as it is not observed in either the dog or man. The erythroid and lymphatic cells constitute 20.1 and 9.0 per cent, respectively, which are about the same percentages as seen in canine and human bone marrow. As was noted in dogs, many of the cells of the myeloid series contain no granules, but identification of the cells is not difficult because of the ease in identifying nuclear structures. A comparison of the bone marrow data with that of Lawrence and co-workers (Table IV) is unsatisfactory since these workers included in their tabulation 26.3 per cent degenerated cells. Their erythroid and lymphoid percentages, however, compare favorably with those obtained by us.

SUMMARY

1. A method is presented describing the technique for obtaining bone marrow from the iliac crest of the cat by aspiration.

2. Data are given showing the cellular constituents in the peripheral blood and bone marrow of normal cats.

3. A comparison of the bone marrow findings in cats with those of dogs and man is made, utilizing the method of aspiration in all three groups.

LABORATORY METHODS

REACTIONS OF VARIOUS PARASITIC ORGANISMS IN TISSUES TO THE BAUER, FEULGEN, GRAM, AND GRAM-WEIGERT METHODS

R. D. LILLIE^{*}
BETHESDA, Md.

IN THE course of some experimental comparisons of the Best carmine method and the Bauer¹ reaction for glycogen, some cat muscle containing Sarcosporidia chanced to be included in the test material. With the Bauer method on low magnification the Sarcosporidia appeared red purple in a pale gray blue background. On higher magnification they were seen to contain numerous red purple granules in their cytoplasm around the nucleus in the equatorial area of fusiform parasites. After salivary digestion according to Bensley² the Sarcosporidia were still red by the Bauer method, while muscle glycogen no longer stained. With Best's carmine method Sarcosporidia do not take the red stain.

This experience led to more extended examination of various tissue parasites by the Bauer method. In most instances it was necessary to use paraffin sections of old material fixed for other purposes in 10 per cent formalin, Orth's fluid, Helly's fluid, or other fixatives.

METHODS

The technique of the Bauer reaction and the composition of the Schiff reagent used for both the Bauer and Feulgen tests were substantially as recently reported.³ By this method glycogen is stained a deep purplish red. The reaction may be prevented by salivary² or by enzyme digestion.³ Cartilage matrix is usually colored a deep reddish purple, contrasting fairly well with the lighter purplish red glycogen in the cartilage cells. Cartilage matrix sometimes remains unstained. The staining of cartilage matrix is not affected by prior salivary, diastase, or ptyalin digestion.

Bauer¹ stated that mucus did not react to this method; however, as Bensley² notes and as we found, in mammalian material, mucus is usually stained purplish pink to light purplish red. This staining reaction persists after salivary, ptyalin, or diastase digestion. Mucous stains well by this method after aqueous formalin or Orth fixations.

Mast cell granules were not demonstrated by either the Bauer or the Feulgen techniques in human, cat, or rat material in which they were readily demonstrable with our azure-cochin technique.

When enzyme digestion tests were used, the digestion was performed on deparaffinized, hydrated sections without collodion treatment and after digestion sections were dehydrated and collodionized as previously mentioned before testing with the Bauer technique. The technique is as recently reported by us.³ For comparison the Feulgen, Gram, and Weigert methods were used as well on most of the material.

The Feulgen technique used herein employed the same Schiff reagent as described by us for the Bauer method³ and followed essentially the procedure outlined by de Tomasi⁴ and by Stowell⁵: Deparaffinize and hydrate sections as usual. Rinse for one minute in N/1 HCl

From the Pathology Laboratory, National Institute of Health.

Received for publication, Oct. 18, 1946.

^{*}Medical Director, United States Public Health Service.

and hydrolyze for twenty minutes at 50° C. in N/1 HCl. Rinse for one minute in cold N/1 HCl and immerse for two hours in Schiff reagent. Give three successive ten-minute baths in closed Coplin jars in acid sulfite mixture (10 c.c. of 10 per cent NaHSO₃, 10 c.c. of N/1 HCl, and 200 c.c. of distilled water). Wash for five minutes in running water. Counterstain briefly (thirty seconds) in 0.02 per cent alcoholic-fast green FCF, dehydrate in alcohols, clear in xylene, and mount in clarite.

The Gram-acetone-safranin technique was as published in 1928.⁶ The Gram-Weigert technique is as follows: Deparaffinize and hydrate as usual. Stain for ten minutes in carbolfuchsin and wash in water. Stain for two minutes in ammonium oxalate crystal violet. Drain, blot, and apply three changes of Weigert's iodine to a time of thirty seconds total. Wash in water. Blot and decolorize with two or three changes of Weigert's aniline xylene (50:50), blotting between changes. Wash in three changes of xylene and mount in clarite.

OBSERVATIONS

Protozoa.—Muscle was resectioned for study from seven monkeys (*Macaca rhesus*), four more cats (*Felis cattus*), two Texas armadillos, one cotton rat (*Sigmodon hispidus*), one mouse (*Macaca musculus*), one ground squirrel (*Citellus beecheyi*), and seven wood rats (*Neotoma micropus*). By the Feulgen method the Sarcosporidia presented small oval red purple nuclei. They were Gram negative and Weigert negative. With the Bauer method there was much finely granular purplish red material about the nuclei of the parasites, so that the affected muscle fibers stood out conspicuously at very low magnifications.

Digestion with saliva, ptyalin, and malt diastase was resisted so that the granules remained Bauer positive in the first cat. Contrariwise, ptyalin and malt diastase digestions completely destroyed the Bauer-positive material in the armadillos, monkeys, wood rats, mouse, cotton rat, and two of the cats, thus identifying it as one of the hexose polysaccharides digestible by those enzymes. In the ground squirrel and the other two cats, most of the colonies lost their Bauer-positive material but some colonies and some individual organisms did not. That this increased resistance to digestion may have been artefact is indicated by the fact that Bauer-positive material remained after diastase digestion only in one of four sections from the ground squirrel tissues.

Further sections from the first cat were subjected to diastase digestion for periods of 30, 60, 90, and 120 minutes. While many Bauer-positive granules remained after 120 minutes, there was a very evident reduction in their number and size, and some cysts contained some or all Bauer-negative parasites. Shorter digestion periods left more and more Bauer-positive material. Altogether it appears that the positive Bauer reaction of these granules in the Sarcosporidia depends on glycogen or a similar polysaccharide.

The brains of nine mice, infected experimentally with toxoplasmosis and fixed in Orth's fluid, were resectioned. In four no parasites were found. In five microcysts containing *Toxoplasma* were identified. The Feulgen reaction demonstrated numerous tiny oval vesicular red purple nuclei in all five. In three of these the Bauer reaction showed many rather vague purplish red granules in a pale blue matrix. In the other two the parasites were apparently Bauer negative. Gram-acetone and Gram-Weigert stains were done on the three Bauer-positive specimens. Parasites were red and pale pink, respectively, by these methods.

Goodpasture stains were done according to Perrin's technique⁷ and in the three brains in which parasites could be found they were stained brown.

After digestion tests with ptyalin and with diastase, *Toxoplasma* still stained red with the Bauer method. The Bauer-positive material was perhaps more clearly demonstrated as a deep purplish red perinuclear deposit, sometimes masking the nucleus; than in undigested material.

Encephalitozoa were found in six of seven mouse brains resected for study. They occurred as oval plump organisms in focal lesions. Some in the Gram stain are longer and slenderer. With this Gram-acetone method they stained pale to fairly deep violet but not blue black. With the Gram-Weigert method the organisms varied from red through purple to violet and sometimes blue black. Feulgen preparations from adjacent sections failed to demonstrate the organisms in the same focal lesions. In Bauer preparations the cells of the focal glioses assumed a vague pink color. Among them there were discerned with difficulty clear, oval refractile bodies of the same size and position as the organisms in Gram-Weigert and Goodpasture preparations. After diastase or ptyalin digestion, however, the organisms were more clearly discerned as oval purplish pink rings with clear centers lying in a light blue background.

The material for study of Encephalitozoon and *Toxoplasma* was resected from animals inoculated with the respective organisms by Perrin.⁷

Examples of endoerythrocytic and exoerythrocytic forms of *Plasmodium gallinaceum* were furnished me by Dr. L. R. Hershberger. In agreement with his usual findings the parasite nuclei stained purplish red by the Feulgen technique. Gram, Weigert, and Bauer reactions were negative.

Sections were recut from the kidneys of twelve mice infested with *Klossiella muris*. In eleven of these more or less numerous parasites were demonstrated. Rosette forms with peripheral budding showed in the buds small oval leptochromatic vesicular nuclei staining light red purple with Feulgen. Clusters of small intratubular round forms were Feulgen negative or contained faintly stained very fine single to multiple granules. In somewhat larger forms Feulgen-positive granules were still lightly stained and usually multiple. In medium-sized round forms dense red purple diplococcoid granules were present dispersed through the cytoplasm. Organisms of this last size were sometimes red purple or less often blue black with the Gram-Weigert technique. Sometimes as many as one-fourth to one-third of the individuals in a given intratubular cluster were so stained, while the rest were Gram negative. With the Gram-acetone method fewer organisms were stained violet or, occasionally, blue black, while other organisms in the same intratubular cluster presented multiple diplococcoid chromatin granules stained red by the safranin counterstain. By the Bauer method most organisms in all animals were Bauer negative. However, in all but one mouse, irregular masses and medium to fine granules of brilliant purplish red material were found in occasional to moderately numerous medium-sized parasites. Liver sections on the same slide in six of eleven mice showed moderate amounts of Bauer-positive glycogen in the liver cells.

Kidney sections from nine of these mice were successfully carried through ptyalin and diastase digestion tests, and the subsequently performed Bauer

reaction revealed in four of them occasional to moderately numerous parasites containing brilliantly purplish red granules. The six livers previously noted had lost all of their glycogen after the diastase digestion and all, or all but traces, after ptyalin.

Trypanosoma equiperdum in methanol-fixed thin blood films is Bauer negative, Weigert negative, and Gram negative. Trophonuclei stain pale purplish red with Feulgen and blepharoplasts were not discerned. However, lymphocyte nuclei are also rather lightly stained. Other fixations might give better results.

Trypanosoma cruzi was demonstrated only in one monkey heart and in two mouse hearts of several resectioned for study. The organisms occurred as the usual *Leishmania* forms in cysts within muscle fibers. Their cytoplasm stained light green, trophonuclei light red, and blepharoplasts as deep red purple rods in Feulgen-fast green FCF preparations. In Gram-acetone-safranin stains blepharoplasts were deep red, trophonuclei light red, and cytoplasm pink. With the Gram-Weigert technique cytoplasm and trophonuclei were pale pink and blepharoplasts deep violet to blue black. The Bauer reaction was negative, though a moderate amount of glycogen was shown in a liver section on the same slide with the one mouse heart and in muscle fibers of the other mouse heart.

Eight cases of amebiasis were resectioned for study. *Endamoeba histolytica* was readily found in all. The organisms were Gram negative and Weigert negative. The nuclei stained relatively faintly by the Feulgen technique. Many amebae contained more or less copious Bauer-positive granular material in their cytoplasm, but in some organisms the cytoplasm was blue gray and vacuolated and in some contained only a few purplish red granules. After diastase digestion all presented blue gray cytoplasm.

This observation extends that of Meriwether⁸ who reported the selective staining of amebae by Best's carmine but did not identify the Best-positive material as glycogen. It would appear from the present observations that *Endamoeba histolytica* often contains glycogen or a similar polysaccharide.

Coccidia (*Eimeria stiedae*) were demonstrated in greater or less profusion in eight of eleven rabbit livers resectioned for study. With the Feulgen method most of the large coarsely granular parasites, whether intraepithelial or free, were Feulgen negative. Some small forms showed red purple granules or green granules with red purple margins. These were not found in five rabbits. In some rabbits there were found, in addition to the typical coccidia, masses of pale green cytoplasm without granules, in which were rings or spirals of small red purple fusiform or bacilliform chromatin granules. With the Gram-acetone technique granules were stained red and shells pink. The Gram-Weigert method gave blue black or deep violet coarse granules in the coccidia, while their shells were stained in varying tones from pink through violet to deep violet or blue black. The Bauer reaction demonstrated a pink to purplish red matrix in the coccidia, in which the refractile or unstained coarse granules were discernible. This material was present also in the coccidia in livers collected six to forty hours post mortem, in which all glycogen had disappeared from the liver cells. Application of Bensley's salivary digestion test to collodionized sections removed the pink matrix in two rabbits, at the same time removing all of the fairly copious

glycogen from the liver cells. In a third rabbit the same test apparently decreased the intensity of the Bauer reaction in the coccidial cytoplasm. Use of the diastase and ptyalin digestion tests on uncollodionized sections also removed Bauer-reacting material from nearly all of the parasites. All glycogen in liver cells was removed by the enzymes.

Bacteria.—Various sections of acute ulcerative appendicitis, of chronic appendicitis, and of animal stomachs and intestines, with or without acute ulcerative lesions, were examined. Various Gram-positive and Gram-negative bacilli and cocci were demonstrated with Gram and Weigert techniques. Gram-positive organisms were more plentiful with the Weigert method. These organisms all failed to stain by the Feulgen and Bauer techniques. However, a few Bauer-positive, Gram-negative branching filamentous molds were seen in a slough in amebic dysentery and in the margin of a cutaneous blastomycotic sinus. Material from five cases of human anthrax was included. The bacilli were usually partly Gram positive and partly negative with the Gram technique. The organisms were Bauer negative. A *Bacillus subtilis* contamination of lung tissue revealed numerous Gram-positive bacilli by the Gram and Weigert methods. The organisms were Feulgen negative and Bauer negative.

A series of four mice inoculated intracerebrally with material under study for the presence of poliomyelitis virus developed empyema of the cerebral ventricles. The pus cells contained a variable small amount of glycogen which was destroyed by the diastase digestion test. In the pus were clumps of small bacilli stained light blue with deep purple (metachromatic) polar granules by the azure eosin stain. With the Weigert stain the bacilli were barred, beaded, bipolar, or solidly blue black. The Bauer method revealed them as slender purplish red rods, which were possibly more distinct after diastase digestion than without it. The Feulgen method failed to stain these diphtheroid bacilli.

Guinea pig spleens and lungs containing numerous tubercle bacilli by the Ziehl-Neelson technique showed no organisms with Feulgen, Bauer, or azure-eosin methods. The bacilli stain blue black by the Weigert and Gram techniques if exposed a sufficient length of time or if heated in the crystal violet solution.

Four chick embryo yolk sacs fixed in Regaud's fluid were resectioned. Azure-eosin stains demonstrated numerous *Rickettsia orientalis* in all. These were not stained in otherwise good Feulgen or Bauer preparations. Tissues of four psittacine birds dead of acute psittacosis were resectioned. Numerous *Rickettsia psittaci* (LCL bodies) were demonstrated with azure eosin; none were demonstrated with the Feulgen method. Fresh sections from four rodents dead of acute tularemia presented numerous organisms in azure-eosin preparations; none presented organisms in Feulgen stains.

Fungi.—Histoplasmosis (*Histoplasma capsulatum*) was studied in the liver and spleen of two dogs and two hamsters, in the lung of a guinea pig, and in the omentum and abdominal wall of a rat. Fixation was with 10 per cent formalin, Helly, or Zenker, all three in one dog. The Feulgen method revealed tiny vesicular light red purple nuclei separated by a clear zone from a pale green capsule. In some of the Zenker-fixed material these nuclei were not demonstrated by Feulgen and stained poorly in comparison with those in formalin-

fixed material from the same dog with the iron-hematoxylin-van Gieson technique. With the Gram-acetone-safranin technique histoplasma nuclei usually stain red to pink; capsules stain paler or much paler. In the rat and in the liver of one hamster a few organisms stained blue black or violet, but most of them were Gram negative. A variable proportion of the organisms were Gram positive when the Gram-Weigert technique was used: none in one animal, few in another, one-third in one, "many" in two, and one-half to two-thirds in one. Usually Gram-positive organisms were stained solidly blue black; however, sometimes only the capsules were stained blue black or violet, while nuclei or nuclei and cytoplasm were stained red by the fuchsin pre-stain.

Results with the Bauer reaction were striking. Organisms were readily identified as fine red purplish rings surrounding a clear zone about the centrally placed, blue or pale blue nucleus. Organisms were more readily found than with azure-eosin or Giemsa stains. After salivary digestion the histoplasma capsules were still Bauer positive. Ptyalin and diastase digestion tests gave the same results in the five animals so tested.

In another subsequently studied animal numerous Bauer-positive rings without central nuclei were found in the foam-cell granulation tissue where no histoplasma could be found with azure-eosin stains. In other areas where histoplasma was demonstrable with the usual azure-eosin stain, the Bauer-positive rings were present in equal numbers and here contained the central blue stained (hematoxylin) nucleus as previously described. This indicates that the sulfurous acid-fuchsin method may be used to demonstrate non-nucleated and presumably dead histoplasma as well as the nucleated and presumably surviving forms. I am indebted to Dr. L. L. Ashburn for the observations on this dog and for material.

Five animals infected with *Haplosporangium parvum* were studied. The tissue studied was lung and was fixed in 10 per cent formalin in four of the animals and in Orth's fluid in the fifth. The animals comprised one rhesus monkey, one cotton rat, and one white mouse, all infected in the laboratory, and two *Perognathus* mice captured in the infected state. In the first three all of the organisms were Gram negative; in the last two a few were Gram positive, most Gram negative with the Gram-acetone technique. With the Gram-Weigert technique a few blue black organisms appeared in one of the first three animals, while in the last two most of the fungi were blue black. The Feulgen reaction revealed no Feulgen-positive material in any of the fungi, though host nuclei were well stained. With the Bauer reaction the capsules of the fungi appeared as thick deep purplish red rings, both with and without antecedent salivary digestion.

Subcutaneous masses from three guinea pigs, fixed in formalin, and brains from 3 mice, fixed in Orth's fluid, were studied in torulosis. In all numerous *Torula histolytica* were present. From 10 to 50 per cent of the yeasts were Gram positive with the Gram-acetone method. The Gram-Weigert method showed nearly all blue black in the three guinea pigs. It was not used on the mouse brains. In the guinea pigs the fungi were apparently Feulgen negative, while in the mouse material small round or oval nuclei were found. These

stained light red purple to pale lilac. With the Bauer method the outer shells of the yeasts appeared as deep purplish red to purplish violet rings. These were apparently somewhat redder in sections subjected to preliminary salivary digestion. Small forms appeared as solid red globules.

A *Peromyscus* mouse and seven white mice experimentally infected with *Coccidioides immitis* were reused for this study. Thirteen blocks from omental and visceral masses, testes, and lungs were used. Fixation was with buffered 10 per cent formalin for the seven white mice and with Orth's fluid for the *Peromyscus*. The fungi were regularly Feulgen negative except on one trial where pink nuclear staining was obtained, and a deteriorated Schiff reagent may have been used for this. Fungi were red by the Gram-acetone-safranin method except for a few blue black endospores in one and a few violet fungi in two of the thirteen blocks. With the Gram-Weigert technique a variable proportion were blue black or deep violet, from as few as one-fourth to nearly all in the several blocks studied. Endospores and small fungi were more often Gram positive than large forms or empty shells. Regularly the thin shells of the mature fungi and the shells of endospores and small fungi were red to red purple with the Bauer technique, and often the fungi contained solid purplish red masses within them, both endospores and larger forms. The five livers observed were glycogen free.

Application of ptyalin and diastase digestion tests to material from five animals reveals that the organisms still presented purplish red shells and endospores when the Bauer reaction was applied after the digestion, but no internal masses staining red persisted.

In Case A-2333, *Monilia candida* endocarditis, numerous small oval yeasts were demonstrated in the mitral thrombus. The yeast cells stained green with the Feulgen method. Within the cells were indistinct or distinct fine granules or delicate tiny rings of material staining purplish pink to red. The yeast cells were nearly all Gram positive by the Gram technique; all stained blue black by the Weigert method and deep purplish red by the Bauer method. After diastase digestion the positive Bauer reaction was unaltered.

Three cases (S-454, S-1187, and S-9410) of eutaneous blastomycosis and one case (A-888) of blastomycotic pulmonary abscesses were studied. The yeast cells were either Feulgen negative, or questionably pale, or very pale red purple nuclei were present. The yeasts were Gram negative, and, by the Weigert technique, only occasional cells stained violet in one of the four cases. The cell walls were stained deep purplish red by the Bauer method, both with and without preceding diastase digestion. Glycogen in epidermal cells and sweat gland cells was destroyed by the diastase.

Kernohan⁹ has previously indicated the presence of a substance stained by Best's earmine method in the capsules of *Histoplasma capsulatum*, *Coccidioides immitis*, *Torula histolytica*, *Blastomyces hominis*, Mucor, and *Monilia*. The present study parallels but does not repeat these findings and further identifies the capsular substance as one resisting enzyme digestion with diastase and ptyalin.

A section of guinea pig omentum with experimental mycetoma was studied. The fixation was with 10 per cent formalin. The organism was *Allescheria boydii*. The tissues contained compact rings of closely felted, refractile brownish yellow, tortuous septate mycelia. The enveloping membrane was more often brown, sometimes blue black, with the Gram-Weigert method. It was unstained by the Gram-acetone method. The Bauer method showed most of the filaments in their natural brown. A few of the most distal, ramifying filaments were red, with or without antecedent diastase digestion. No chromatin was demonstrable with the Feulgen method.

Formalin-fixed liver and spleen from a rabbit infected with *Aspergillus fumigatus* presented Gram-negative mycelia with the Gram-acetone technique. With the Gram-Weigert method part of the mycelia were blue black and part red. With the Bauer method a very delicate red to purple capsule was recognized outside a violet protoplasm and crossing at the septa. This Bauer-positive material resisted salivary and diastase digestions.

The mycelia of chromoblastomycosis in the formalin-fixed omentum of a rat were partly blue black, partly red, and partly brown by the Gram-Weigert method. Staining was apparently restricted to an outer capsular substance, so that the mycelia appeared as hollow tubes. With the Gram-acetone and the Bauer techniques the mycelia apparently retained their natural brown color for the most part. Some filaments and, especially, spore-like enlargements presented Bauer-positive walls, particularly after diastase digestion.

In Case S-8442, mycetoma of wound of hand, the granules were Feulgen negative and Gram negative with the Gram-acetone method. By the Gram-Weigert technique there were few to moderately numerous ramifying septate Gram-positive mycelia. These appeared foamy, vacuolated, or barred blue black on a pink background. With the Bauer method the granules were composed of a dense felt work of light purplish red hollow, rather thin-walled tubules, which remained Bauer positive after diastase and ptyalin digestion.

In Case S-14788, *Cephalosporium* mycetoma, the granules were again Feulgen negative and Gram negative with the Gram-acetone method and again contained a few branching, foamy, vacuolated, or solid blue black mycelia by the Gram-Weigert method. The Bauer reaction again revealed a close feltwork of light red purple tubules, which remained Bauer positive after diastase digestion.

In Case A-2884, *Cephalosporium* mycetoma, multiple sections of sinus tracts presented numbers of large granules composed of wide dichotomously and laterally branching mycelia with frequent transverse septa and scattered bulbous enlargements to twice ordinary width and about three the mycelial width in length. These bulbous enlargements were relatively thick walled. The margin was partly composed of bulbous enlargements similar to the foregoing in structure. The mycelia and bulbs were Feulgen negative and Gram negative. With the Weigert stain part of the mycelia were stained pink, part presented violet walls, and some presented transverse blue black bars. Some violet walled mycelia ramified beyond the hyaline Gram negative-matrix into the surrounding

pus. With the Bauer method the mycelial walls and septa stained deep purplish red, with or without antecedent diastase digestion. The mycelia were not acid fast.

In Case A-3072, *Penicillium* species abscess of lung, imbedded in the pus of the abscess cavities and in giant cells were fragments and radiating stellate masses of broad septate mycelium with closely spaced septa, scattered bulging thicker-walled segments, and separate oval yeast-like globules similar in short diameter to the bulging segments. Lateral and dichotomous branching were observed. Mycelia were "negative" to the Ziehl Neelson, Feulgen, and Gram methods. Most filaments stained pink; a few stained violet, and occasional ones were solidly or barred blue black by the Weigert method. Bauer stains, both before and after diastase digestion, colored the walls and septa a deep purplish red.

Four cases of actinomycosis (A-478, A-1914, S-12263, and A-2187) and one case of maduramycosis (S-17813) presented more or less numerous granules composed of a central feltwork of narrow mycelial threads and a peripheral hyaline matrix whose outline varied from granule to granule in each case from smooth or lobate to tongue-like narrow prolongations with bulbous tips. The mycelial threads only infrequently presented dichotomous branching. They were Feulgen negative. Many stained blue black, some solidly, some barred or beaded, and some red with the Gram method, and nearly all were blue black by the Weigert method. The hyaline matrix and border was Gram negative by both methods. With the Bauer method some granules presented a vague purplish pink granular deposit centrally; in some this purplish pink material was vaguely filamentous, and in a few more sharply defined purplish red filaments were discerned. After diastase digestion vague and definite filaments were often more readily discerned.

Of the foregoing cases, only the last was studied culturally.

In Case S-22853, mycotic gastric ulcer, the Gram-acetone method revealed a profusion of red filaments and fine and coarse rods in the ulcer base. A minority of these organisms were blue black by the Gram-Weigert method. The filaments and rods were unstained by the Feulgen and Bauer methods.

Sufficient material from one case only of botryomycosis (S-11861) was available for restudy. One to several "granules" were found in suppurating sinuses in each of the five sections. Azure-eosin stains revealed a hyaline eosinophilic border zone, marginally serrate, lobate, or bulbous. Next within this was a zone of densely packed cocci, sometimes poorly stained and sometimes deep blue. The centers were composed of more or less closely packed, deeply basophilic cocci lying in clusters, pairs, or short chains. With the Gram stain the cocci were Gram positive in some granules and Gram negative in others. By the Weigert method there were always considerable numbers of closely and loosely packed Gram-positive cocci occurring in clusters and lying in a hyaline pink matrix. The marginal serrate or club zone was hyaline and stained pink to fairly deep red.

By the Bauer method, with and without antecedent diastase digestion, the granules stood out under low magnification as conspicuous purplish red

masses. The border or club zone stained pale gray or blue gray. The coeci appeared as pale blue bodies. Among the coeci were numerous fine red granules and short and narrow red bacilli, fewer pale pink rods containing red granules, and a few longer red filaments which occasionally showed branching. Bacillary and filamentous structures were best discerned in marginal areas. Central areas presented too much vague red granular material to permit discernment of detail. Occasionally coarser pink filaments with clear centers were discerned, and in cross section these appeared as pink to red rings about the same size as the coeci. Red filaments and bacilli were perhaps $0.5\ \mu$ in thickness; coeci were about 1 to 1.5 microns.

The existence of small bacillary and occasionally filamentous Bauer-positive elements in the granules of this case of botryomycosis in addition to the usually described Gram-positive staphylococci is a matter of interest requiring further investigation to decide as to its possible etiologic significance.

Metazoa.—Tissues from eight animals were resectioned for study and Schistosome eggs were demonstrated in seven of them. Two species, *Schistosoma mansoni* and *Schistosoma japonicum*, were included in the material, and the animals included six experimentally infected hamsters and a naturally infected dog. Some adult parasites were found in veins. Nuclei of adult parasites and embryos were red purple by the Feulgen method, just as were the host cell nuclei. With the Gram-acetone technique the shells were usually pink but sometimes pale violet. With the Gram-Weigert method the shells varied from pink to blue black, being perhaps most often violet. Using the Bauer technique the shells were usually deep purplish red. Fragmenting shells stained similarly and the granulomata surrounding fragmenting eggs or replacing them often contained globules and masses of purplish red to purplish pink hyaline material in the cytoplasm of the epithelioid cells. After diastase and ptyalin digestion tests the shells of the ova still stained red purple with the Bauer method, but the cytoplasm of the epithelioid cells became Bauer negative.

The implication that the cells of the granuloma convert the chitin of the Schistosome eggshells into a polysaccharide which is digestible by ptyalin and by diastase, while the chitin itself is not so digestible, appears to warrant further study.

The livers of four wild rodents infected with numerous doubly operculate eggs of *Capillaria (Hepaticola) hepatica* were resectioned for study. The infected animals were a woodchuck (6240), a cottontail rabbit (8385), a jackrabbit (8788), and a squirrel (8789) from Western Montana. These ova, when stained with azure eosin, presented several blue nuclei, coarsely granular pink cytoplasm, a hyaline, refractile inner shell, and a refractile, radially striate outer shell. The operculae appeared as apparently open spaces. The embryo nuclei stained purplish red by the Feulgen method, the refractile inner shell was tinted yellow to orange, and the cytoplasm and the radially striate outer shell stained green. With the Gram stain the refractile inner shell stained pink to violet, the cytoplasm was largely pink, sometimes containing violet granules, and the outer shells were refractile to pale pink. The nuclei stained red. With the Weigert method the refractile inner shell stained deep red, the operculae were filled by

deep violet to blue black plugs, the cytoplasm was violet to pink, and the radially striate outer shell was pink. Diastase and ptyalin digestions did not appreciably alter these reactions.

Inner and outer shells remained unstained or yellowish by the Bauer method, the operculae were filled by deep purplish red plugs, nuclei were blue, and cytoplasm was granular and light purplish red or less often light blue. Diastase digestion rendered the cytoplasm of most of the eggs Bauer negative; ptyalin was less effective but still destroyed most of the Bauer-positive granular material in the cytoplasm. The opercular plugs still stained deep purplish red after digestion with either enzyme.

In a Norway rat (1364), cysticercosis of liver, most of the cyst walls and cestode tissues were Gram negative, Weigert negative, and Bauer negative. In one section, apparently scolex, much granular purplish red material was present in the cestode tissue with the Bauer method, and the Weigert preparation gave violet granules in the same location. This section possessed the most Feulgen-positive nuclei, but fair numbers of these were present also in the cyst walls. After ptyalin and diastase digestion tests the Weigert-positive material was destroyed, and the Bauer-positive material in the scolex persisted after ptyalin but not after diastase digestion.

In a snowshoe rabbit tapeworm (15720), the calcareous globules were deep blue by azure eosin, violet with Weigert, and unstained by the other methods. Nuclei were stained purplish red with the Feulgen technique. The cuticle was deep blue with azure eosin and red with Weigert and Gram techniques. The Bauer preparation showed numerous granules and globules of purplish red material in the stroma. After a ptyalin digestion test this material became Bauer negative. Similarly, Bauer¹ has shown the presence of glycogen in stroma cells and elsewhere in *Fasciola hepatica*, using iodine, Best and Bauer methods, and salivary digestion tests with the two latter stains.

In Case S-4147, appendix containing *Trichuris* and *Ascaris* eggs, the eggs appear yellow by the Bauer method, brown to yellow by the Feulgen, pink to red by Gram-acetone, and their shells stained red to purple by Gram Weigert.

In Case S-18128, *Onchocerca volvulus* in skin, the chitin of adults stained pale reddish purple with the Bauer method, whereas the same parasites contained numerous Feulgen-positive nuclei. Feulgen-negative (dead?) parasites gave a denser red purple chitin stain with the Bauer method. The chitin was Feulgen negative, Gram negative, and Gram-Weigert negative.

SUMMARY

Sharply stained nuclei were demonstrated by the Feulgen method in the following: *Sarcosporidia*, *Toxoplasma*, *Klossiella muris*, *Trypanosoma cruzi*, *Plasmodium gallinaceum*; in eggs, larvae, and adults of *Schistosoma japonicum* and *Schistosoma mansoni*; in larvae and adults of tapeworms, roundworms, and *Onchocerca volvulus*; and in eggs and larvae of *Capillaria hepatica*. Poorly stained or dubiously Feulgen-positive nuclei were encountered in *Encephalitozoon*, *Eimeria stiedae*, *Endamoeba histolytica*, *Torula histolytica*,

Blastomyces, and *Histoplasma capsulatum*. The mycelial fungi, bacteria, rickettsiae, *Coccidioides immitis*, and *Haplosporangium parvum* failed to present Feulgen staining material.

Differences between the Gram-acetone method and the Weigert-aniline xylene-Gram variant were generally in the direction that the latter yielded more Gram-positive organisms. *Eimeria stiedae*, almost completely Gram negative by the acetone technique, regularly contained numerous conspicuous Weigert-positive granules. One-fourth to two-thirds of the cells of *Histoplasma capsulatum* in any given preparation were Gram positive by the Weigert method, while all were negative by the acetone method. *Haplosporangium*, *Torula*, and *Coccidioides* all showed many more Gram-positive cells with the Weigert method. *Klossiella muris* often presents Gram-positive cells by the Weigert method, seldom with the acetone method. *Encephalitozoon* is weakly positive by the acetone method, while negative and strongly positive cells are seen side by side in Weigert preparations. Mycetomal and other thick mycelial fungi often present some positive filaments with the Weigert method and none with the acetone. Weigert-positive, Gram-negative material is seen in the shells of *Schistosoma* eggs and in the opercular plugs of *Capillaria* eggs.

Bauer-positive polysaccharides digestible with ptyalin and malt diastase are present in the cytoplasm of *Endamoeba histolytica*, *Eimeria stiedae*, most Sarcosporidia, and in the egg cytoplasm of *Capillaria hepatica*.

Bauer-positive material which resists digestion by ptyalin and malt diastase forms the capsules of the following: certain yeasts, such as *Monilia candida*, *Histoplasma capsulatum*, *Torula histolytica*, *Haplosporangium parvum*, *Coccidioides immitis*, and *Blastomyces* species; certain coarsely mycelial fungi, such as those of mycetoma, *Penicillium*, *Aspergillus*, and others; the shells of the eggs of *Schistosoma mansoni* and *Schistosoma japonicum*; and the opercular plugs of the eggs of *Capillaria hepatica*. Bauer-positive, relatively enzyme-resistant granules are found in some Sarcosporidia, in a few individuals of *Klossiella muris*, and in *Toxoplasma*.

The ray fungi possess small quantities of diffuse material reacting to the Bauer test, which often appears more definitely filamentous after enzyme digestion tests. Similar bacillary and occasionally filamentous Bauer-positive material was found among the staphylococci in the granules in a case of botryomycosis. Some Gram-positive diphtheroid bacilli are also Bauer positive, with or without diastase digestion.

The Bauer method offers a valuable aid in detection of scarce amebae and yeastlike fungi in tissues. It gives structural details in the more coarsely mycelial fungi which are not apparent with other usual staining methods. It clearly demonstrates the remaining fragments of *Schistosoma* eggs in granulomata in which they are not readily identifiable by other means.

In its possession of a Bauer-positive, enzyme-resistant capsule and in its partially Gram-positive reaction *Encephalitozoon* shows a certain resemblance to *Coccidioides* and to *Histoplasma*. Wenyon¹⁰ has stated that "in many respects it resembles a small yeast, but reproduction by budding has not been observed." He further states that "It seems premature to conclude that the organism is

even a protozoon." The present data tend to accentuate the doubt of the protozoal nature of this organism. It is noteworthy that both *Coccidioides* and *Histoplasma* were first thought to be protozoal.

A SIMPLE METHOD OF STAINING MALARIA PARASITES

GEORGE JOANNIDES, M.D.

ATHENS, GREECE

THE report by Manwell* incites me to report another simple method for staining malarial parasites which was used during the war when no Leishman, Wright, or Giemsa's stains were available and when buffered or distilled water could not be obtained.

In a 50 c.c. porcelain evaporating dish, place 0.5 Gm. methylene blue and 1.5 Gm. borax. Add, with stirring, 30 c.c. of boiling tap water. Place the evaporating dish over a small flame at such a height as to maintain a temperature of 75 to 80° Centigrade. The liquid evaporates almost to dryness in approximately one-half hour. Add 30 c.c. of boiling tap water for a second and a third time, evaporating after each addition. Set aside for twenty-four hours. A dry blue compact mass remains in the evaporating dish. Add, without stirring, 30 c.c. of 95 per cent alcohol. After five minutes pour the alcohol into a 100 c.c. bottle and let the residue in the evaporating dish dry almost completely. Repeat the extraction in the same way, once with 30 c.c. and once with 40 c.c. of alcohol. The total alcoholic extract (about 100 c.c.) is blue and contains no precipitate.

On the unfixed blood film, place 15 drops of the alcoholic stain. After thirty to sixty seconds add 15 drops of a 1 to 2000 solution of eosin in tap water. Mix the stains on the slide by means of a glass rod. After three to four minutes flood the slide with tap water, wash with tap water, and let dry. The red cells appear light green with a pinkish cast, the eosinophile granules stain pink, and the remaining leucocytes and the platelets stain as with Giemsa's stain. The malarial parasites also have the same appearance as when treated with Giemsa's stain but are stained somewhat less deeply.

The satisfactory results obtained by this method are probably due to: (1) nearly complete transformation of methylene blue to azure; (2) the greater solubility in alcohol of the azure as compared to the methylene blue solubility; and (3) the insolubility of borax in alcohol. The technique constitutes a combination and modification of older ones published by many authors.

From the Pasteur Institute.

Received for publication, Sept. 23, 1946.

THE USE OF RUSSELL VIPER VENOM AS A MEANS OF FOLLOWING THE ANTICOAGULANT ACTION OF 3,3'-METHYLENEBIS (4-HYDROXYCOUMARIN) IN THE DOG

EDWIN J. DE BEER
TUCKAHOE, N. Y.

WITH THE TECHNICAL ASSISTANCE OF ROCCO FANELLI

FULLERTON,¹ Page and Russell,² Shapiro and co-workers,³ and others have shown that when Russell viper venom was substituted for thromboplastin in Quick's⁴ prothrombin time test, certain points of resemblance could be noted. The purpose of this paper is to present comparative data obtained by the action of each of the two clotting accelerators on the plasma of dogs treated with 3,3'-methylene bis (4-hydroxycoumarin) (Dicumarol).⁵

Link and associates^{5, 6} have shown that dicumarol is probably responsible for the hemorrhagic action of spoiled sweet clover hay. It is believed generally that the drug acts by reducing the effective prothrombin level. In fact, Quick's prothrombin time test was used to guide the isolation work. Without attempting to review the literature in the clinical field, it may be stated also that thromboplastin has been frequently employed to follow the course of dicumarol therapy.⁷⁻⁹ Russell viper venom also has been used for this purpose, and among its users may be mentioned the names of Shapiro and Sherwin⁸ and Wright and Prandoni.¹⁰

METHODS

Blood was obtained from dogs by venipuncture, decalcified by mixing with 2 mg. of dry potassium oxalate per cubic centimeter of blood, and centrifuged promptly. The clear plasma was diluted by adding 3 volumes of 0.9 per cent NaCl and the prothrombin time determined on one portion with 2.5 per cent thromboplastin as described by Quick.⁴ A commercial preparation prepared from rabbit brain was used for this purpose. This concentration of plasma (25 per cent) was found to be well suited for use with Russell viper venom since it yielded times of convenient length. Much longer times were obtained with thromboplastin at the maximum dicumarol effect. It may be noted that times may be shortened for both thromboplastin and Russell viper venom by increasing the plasma concentration or they may be lengthened by diluting the plasma.

A second portion was tested with Russell viper venom instead of thromboplastin. In carrying out this determination, 0.1 c.c. of the 25 per cent plasma was mixed with 0.1 c.c. of 1:10,000 Russell viper venom† and 0.1 c.c. of 1 per

From the Wellcome Research Laboratories.

Received for publication, June 17, 1946.

*Dicumarol is the trademark for a commercial preparation of 3,3'-methylene bis (4-hydroxycoumarin).

†Supplied as Stypven Brand Russell Viper Venom by Burroughs Wellcome & Co. (U. S. A.) Inc., New York, N. Y.

cent calcium chloride was then added. A stop watch was started at the instant of the addition of the calcium chloride and stopped when the first flecks of fibrin appeared. For the sake of convenience this elapsed time interval will be known as the RV time. All determinations were made in triplicate. Eight different dogs were used in these experiments.

Dicumarol in gelatin capsules was given orally.

RESULTS

The results of a typical experiment are given in Table I. It will be observed that the RV times paralleled the prothrombin times in several respects. Both coagulating agents simultaneously revealed the onset of dicumarol action, both indicated about the same duration of action, and both showed peaks of maximum intensity at about the same time. It will be observed that the thromboplastin figures rose to relatively higher values. Also thromboplastin figures fell to relatively lower levels during the reaction period which lasted for two or three weeks after the dicumarol administration.

TABLE I. RELATIONSHIPS BETWEEN DICUMAROL ADMINISTRATION, PROTHROMBIN TIME, AND RV TIME IN DOG

DATE	MEAN RV TIME (SECONDS)	MEAN PROTHROMBIN TIME (SECONDS)	DICUMAROL DOSAGE (MG. PER KG.)
11/15	28.3	31.1	10
11/16	40.5*	57.3*	10
11/17	46.6*	314.0*	10
11/18	71.4*	>900.0*	--
11/20	107.0*	>900.0*	--
11/22	62.4*	182.0*	--
11/24	40.3*	31.3	--
11/25	28.0	34.1	--
11/27	31.3	30.4	--
12/11	21.8	18.3	--
12/12	23.2	17.1	--
12/14	21.2	13.1	--
12/16	24.0	14.7	--
12/18	24.8	13.9	30
12/19	38.8*	26.9*	--
12/20	49.8*	56.3*	--
12/21	50.3*	121.0*	--
12/22	56.3*	433.0*	--
12/23	61.8*	133.0*	--
12/26	34.5*	20.2	--
12/27	29.2	17.8	--
12/29	26.6	17.7	--
1/1	29.8	20.1	--

All determinations were done in triplicate on 25 per cent dog plasma.

*Values significantly above the normal level.

These experiments confirmed the earlier observations of Butt and associates⁷ that divided doses of dicumarol were more effective than the same quantity administered in a single dose.

In considering the significance of the effects produced by dicumarol, account must be taken of the reproducibility of the test and the fluctuations in normal levels. Both thromboplastin and Russell viper venom gave highly consistent values. The total range experienced in triplicate determinations is rarely more than one or two seconds. Normal times, however, vary from

dog to dog, and Fig. 1 gives an example of how times may vary within the same animal. If the data of November 15, 25, 27, December 11 to 18, 27, 29, and January 1, as given in Table I, be considered as normal values, it will be seen that the RV times for this animal varied about a mean of 26.2 seconds. The standard deviation of these eleven values was 3.4 seconds. It is commonly assumed that any sample which breaks through a range embraced by the mean ± 2 times the standard deviation should be considered significantly different. In this case the upper limit would be $26.2 + (2 \times 3.25)$ or 32.7 seconds. If this figure be taken as a guide, it is apparent that the administrations of dicumarol were followed by significant increases in RV times.

Fig. 1.—The effect of dicumarol on the RV time of dog plasma. D, Dicumarol in milligrams per kilogram.

SUMMARY

Russell viper venom resembled thromboplastin in its ability to follow the course of the antieoagulant action of 3,3'-methylene bis (4-hydroxycoumarin) in the dog.

The times for the formation of clots by thromboplastin were relatively longer than the times for the formation of fibrin flecks by Russell viper venom.

MICROANALYSIS OF OPIATES BY X-RAY DIFFRACTION*

S. T. GROSS,† URBANA, ILL., AND FRED W. OBERST,‡ LEXINGTON, KY.

SINCE the development of various derivatives of morphine and the ultimate study of many of them in man and animals, it has become more difficult to find chemical tests suitable for their identification and determination in amounts present in biologic materials after administration. Occasionally toxicologic examinations of the lesser known opium derivatives require other than chemical means for a specific and conclusive identification.

The x-ray diffraction method has been used successfully for many years as a critical, characteristic means of identification, but it has not found application in many fields where only extremely small amounts of materials are available for analysis. Its advantages have led us to develop microdiffraction techniques of sufficient sensitivity that practically any sample of crystalline material may be identified and determined quantitatively. The new methods of identification serve not only to adapt small samples for diffraction information but include topochemical reactions in the preparation and examination of derivatives.

METHODS

The flat cassette method of x-ray diffraction was employed in the present experiments (Fig. 1). The x-ray beam, collimated to a thin pencil of radiation about 0.010 inch in diameter, was allowed to penetrate the sample, and the diffraction pattern was recorded on a flat film mounted perpendicularly to the x-ray beam and separated from the sample by 5 centimeters. The sample holder was a small metal disk perforated with an opening $\frac{1}{64}$ inch in diameter in which the sample (about 0.08 mg. or 80 γ) was packed. X-radiation from a copper target diffraction tube, filtered through 0.001 inch nickel foil, was used; exposures were two hours at 14 ma. and 40 kv. peak. Data are tabulated in terms of interplanar spacings or "d" values, where "d" is defined by the Bragg law,

$$d = \frac{\lambda}{2 \sin \Theta}.$$

The wave length of x-radiation used (λ) is essentially 1.54 A.U.; 2Θ represents the angular deviation of the diffracted x-ray beam from the undiffracted beam (Fig. 1). Intensity values were estimated with a Leeds and Northrup recording microphotometer. No attempt was made to correct for absorption of the x-ray

Received for publication, Sept. 19, 1946.

*The x-ray work was carried out in the Department of Analytical Chemistry at the University of Illinois. The drugs used in the test were prepared by Dr. Lyndon F. Small, formerly of the University of Virginia and now at the National Institute of Health, while participating in the work of the Committee on Drug Addiction of the National Research Council.

†Formerly with the Noyes Laboratory of Chemistry, University of Illinois; now with the General Aniline and Film Corporation, Easton, Pa.

‡Formerly Biological Chemist, Research Department, United States Public Health Service Hospital; now with the Wm. S. Merrell Company, Cincinnati, Ohio.

beam in the samples, although samples were made as thin as possible to obviate this factor. Intensity values listed are comparable only with patterns made by the flat cassette method, although "d" values are identical within experimental error with those obtained from any type of x-ray powder diffraction pattern technique.

A single pattern is acceptable identification when exact coincidence with a reference is obtained, but the use of two patterns of an alkaloid (one of the base and one of its hydrochloride salt) renders the result conclusive. Such reactions are readily carried out topochemically as follows: After a pattern of the free base is obtained, the mounted sample may be exposed to hydrochloric acid fumes for a short time. This converts the base to the hydrochloride salt (as shown by the absence of the diffraction lines of the base), and the second diffraction pattern may be obtained. If the starting material were the hydrochloride, exposure to ammonia fumes will convert it to the free base.

Fig. 1.

These gas treatments are conveniently carried out by rinsing a beaker with concentrated hydrochloric acid or with ammonium hydroxide, as desired, and inverting it over the sample mounted in the holder for twenty to thirty minutes. The sample holder must be constructed of material which will not react with the fumes; otherwise, it is necessary to remove the sample from the holder and

replace it later. The pattern of ammonium chloride formed in the sample will appear on subsequent diffraction patterns, but does not interfere with the identification.

RESULTS

X-ray Diffraction Patterns of Several Opiates and of Demerol.—The data given in Table I are arranged for classification according to the system employed by Hanawalt¹ in his tables for the identification of unknown materials by the diffraction method. Roman numerals I, II, and III, following intensity values, correspond to the three strongest lines in the order of their intensity. Symbol B indicates that the line is unusually broad, and brackets are employed when two lines are so close together that slight changes in experimental conditions might make them appear as a single diffraction interference.

Fig. 2.—Patterns made with filtered copper K-alpha radiation; sample—film distance, 5 cm.; two-hour exposure, 20 Ma. and 40 kv. A, morphine base; B, morphine hydrochloride; C, morphine sulfate dihydrate; D, morphine sulfate pentahydrate; E, heroin base; F, heroin hydrochloride.

The characteristic experimental measurements for a number of opiates and for Demerol* are listed in Table I; example prints are shown in Fig. 2. Attention is directed to the patterns of two hydrates of morphine sulfate, the one be-

*This drug was furnished by Dr. O. W. Barlow, formerly of the Winthrop Chemical Company, Inc., New York, N. Y.

ing a dihydrate and the other a pentahydrate.* The pattern obtained after heating the pentahydrate of morphine sulfate between 185 and 195° C. for two hours is also included in the table. This pattern is reproducible and probably represents largely the anhydrous form, although it may also contain some other decomposition products. This pattern is not accounted for by combination of the two hydrates.

Fig. 3.—A, Diffraction pattern of urinary residue after heroin administration, showing presence of morphine (small amount of magnesium oxide added). Exposure made seven hours. B, Diffraction pattern of 0.7 γ morphine suspended in 0.06 mg. magnesium oxide.

Detection of Morphine in Urine by X-ray Method.—In Fig. 3A is shown the diffraction pattern of an alkaloid present in a residue prepared from urine of an addict receiving heroin.† Comparison with Fig. 3B shows that this product is largely morphine; no heroin could be detected. This is in accord with excretion studies previously reported.³ The total amount of sample available in this case was about 0.98 milligram. The spots on the pattern indicate that the material was present as crystals with particle size greater than about 10^{-3} centimeters. Below this dimension the lines are sharp and smooth until colloidal dimensions are attained. In either case the position of the diffraction lines is unchanged.

Since urinary residues containing morphine, etc., are rather hygroscopic, they should be examined under conditions of reduced humidity.

DISCUSSION

The described method of identification by x-ray diffraction technique is accepted as definite, especially when based upon two diffraction patterns. It is not

*The results on two hydrates of morphine sulfate are worthy of mention. Patterns obtained from a single commercial sample were not identical with those of Dr. Howard L. Andrews of the National Institute of Health. This stimulated further examination of seven additional samples; three of these gave the same pattern as ours and four were identical with those of Dr. Andrews.

Dr. Andrews⁴ heated the pentahydrate of morphine sulfate at 57° C. for two hours and then made an x-ray pattern in a sealed tube. A mixture of the two patterns was obtained. Heating the pentahydrate at 60° C. for two hours gave a compound having a pure pattern agreeing with our original one. When the tube was left open for a few hours, the diffraction pattern returned to the form found for the pentahydrate. Weight loss determinations made by Dr. Andrews indicate that the change in patterns is accompanied by a loss of 3 molecules of water. It is believed that one pattern is obtained from the pentahydrate and the other from the dihydrate.

†The alkaloid excreted in urine was extracted by means of a chloroform-alcohol mixture (3 and 1 parts, respectively) according to the technique described by Oberst² using a liquid-liquid extractor. After evaporation of the solvent the residue was subjected to isoelectric extractions. The residue obtained after evaporation of the organic solvent was then treated with permittit to separate morphine from undesirable substances extracted. The permittit was washed and then treated with alkali to remove morphine which was re-extracted with the chloroform-alcohol mixture. After evaporation of the solvent the residue was weighed and submitted to x-ray examination.

After the numbers, I, II, and III represent the three strongest lines in order of their intensity; B indicates an unusually broad line; and brackets are used to indicate two lines which are barely resolved.

limited to alkaloids; any crystalline material may be so identified. Patterns of a number of alkaloids have been prepared by one of us (S. T. G.), and the topochemical method of preparing salts, or the free bases, works quite as well as with the opium alkaloids shown in Table I. Such identifications are of definite toxicologic interest, since the material used is not consumed, the identity is certain, and the diffraction patterns serve as permanent records.

It is possible to obtain diffraction patterns with extremely small amounts of material by using a small sample holder and a very thin powdered sample. Even smaller samples may be used if some inert material, comparatively transparent to the radiation, is added to support the alkaloid. With such a mixture the morphine pattern has been obtained with as little as 0.0007 mg. (0.7 γ) of morphine in the sample. Only the strongest lines are present in patterns containing such small amounts of alkaloid (Fig. 3B). It is necessary that the mounted sample contain at least 1 per cent of morphine; hence, overdilution with the inert material must be avoided. Such a sample was prepared by mixing the free alkaloid in an aqueous suspension with a weighed amount of magnesium oxide to give a thorough dispersion of the insoluble alkaloid. After drying, a small amount of the weighed mixture was used for the sample mount. Reaction between the magnesium oxide and water is quite negligible.

Experiments were carried out by precipitating the base with ammonium hydroxide fumes from a solution of an alkaloidal salt in the presence of a suspension of magnesium oxide. This method is also satisfactory, but diffraction lines from addition products, which must be recognized and discounted, complicate the pattern.

By addition of some known material in a definite proportion to a sample, it is possible to test for the alkaloid quantitatively. Such a quantitative micro-estimation requires a comparison of line intensities and a correction factor. As a description of this method has been published,⁴ details will not be given here. The flat cassette type of pattern is suitable for such an analysis, which makes it possible to determine all important constituents of a mixture from one diffraction pattern, provided the necessary reference data are available.

Advantages of the x-ray diffraction technique over other methods of identification are: (1) characteristic and specific diffraction patterns are obtained for any given substance, (2) employment of extremely small amounts of material is possible, (3) a permanent record is obtained, (4) the sample is not destroyed, (5) samples need not be pure (only a small percentage of the material being necessary for identification in the absence of heavy absorbing inorganic salts), (6) all of the materials may be identified in mixtures, although the analysis is more tedious than in the case of a simple compound, and (7) quantitative estimation is possible with a very small change in procedure. Among the disadvantages of this technique, mention should be made of the fact that the presence of either solid solutions or colloids may give unsatisfactory results; however, this condition was not encountered with the materials used in the present study. It is necessary to have standard patterns, or data such as are given in this paper, to carry out the identification.

SUMMARY

A micromethod for a conclusive identification of various alkaloids, either singly or in mixtures, is described. The specific data necessary for identification of a number of the opium alkaloids are listed in a suitable form for general usage. The sensitivity of the method has been shown to be sufficient to detect and identify quantities of alkaloid as small as 0.0007 mg. (0.7 γ).

A method is described for converting the free base of an alkaloid to a salt in the sample holder without loss of material, whereby two diffraction patterns, rather than one, are used to make identification conclusive.

The authors wish to acknowledge their indebtedness to Dr. Lyndon F. Small, for supplying many of the opiates studied, and to Dr. Howard L. Andrews and Dr. Small, for reading the manuscript and offering helpful suggestions.

A METHOD OF BONE MARROW BIOPSY FROM THE RAT*

I. MYRON VIGAN, M.D.†

ROCHESTER, MINN.

IN STUDIES of experimental anemia it is frequently essential to observe cytologic changes which occur within the bone marrow. In connection with a recent study of the effects of synthetic folic acid (folvite) on certain experimentally induced anemias, some procedure which permitted frequent sampling of the bone marrow in individual rats was essential. Since this procedure has proved most satisfactory and since I am aware of but one published method‡ for obtaining specimens of bone marrow from small animals, I believe that a report of this technique may be of interest to hematologists.

Fig. 1.—Technique of obtaining bone marrow. *a*, Incision of skin and fascia, separation of fibers of biceps, and opening in femur. *b*, Enlargement of opening. *c*, Pipette. *d*, Insertion of pipette. *e*, Closure of incision.

The procedure may be performed quickly, usually requiring less than ten minutes. Anesthesia is induced with an intraperitoneal injection of pentobar-

bital sodium in amounts equal to 30 mg. per kilogram of body weight. Ether anesthesia may also be used. The rat is placed on an operating board in a prone position and the hair over the lateral aspect of the thigh is clipped. An incision approximately $\frac{1}{2}$ inch (1.3 cm.) in length is made through the skin and fascia directly over the distal third of the femur. The fibers of the short head of the biceps muscle are then carefully separated by means of a small hemostat, thereby exposing the femur. The muscle fibers on either side of the bone are retracted with small aneurysm needles and the periosteum of the femur is stripped away. Using a crosscut dental bur (No. 560), a small opening is made through the cortex into the marrow cavity (Fig. 1*a*). The circular opening is then slightly enlarged in the direction of the longitudinal axis of the bone, forming an oblong aperture which readily permits the insertion of the tip of an especially designed pipette into the marrow space (Fig. 1*b*). The pipette, which previously has been rinsed with a solution of heparin, is passed through the opening so that its tip lies in the marrow space parallel to the long axis of the bone (Fig. 1*c* and *d*). A small quantity of the marrow is then orally aspirated. Appropriately sized drops are placed on clean glass slides and films are made in the usual manner.

The incision is closed with a single cotton suture extending through the skin into the deep muscles (Fig. 1*e*). Untoward aftereffects are seldom noted, and the incision is usually well healed within a week. The slides are stained with MacNeal's tetrachrome stain. The procedure may be repeated within a week on the opposite femur and within three weeks on the original one.

THE USE OF DRIED ANTIGEN PREPARATIONS FOR TESTING PNEUMOCOCCUS TYPING SERA

JANET M. BOURN, PH.D., AND CHARMION M. CARNES, A.B.

THE testing of pneumococcus typing sera for specific and cross reactions according to the requirements of the National Institute of Health served to stimulate the study reported here. The problem was to find a way of preserving pneumococcus typing antigens for a period longer than four days and to demonstrate the successful use of such antigens.

The directions for the preparation of pneumococcus antigens, as given by the National Institute of Health,¹ may be summarized as follows: Each antigen used is a young (one to five hour), fully virulent broth culture to which 1.43 per cent commercial formalin has been added and which has been checked for capsular swelling and agglutination with homologous antiserum. The antigens should be kept in a cold room when not in use and in an iced container when in use. The antigen may be used as long as the pneumococci stay in suspension and the swollen capsules appear intact and are not fragmented, usually a period of three or four days.

The use of dried antigen preparations as a means of preserving pneumococcus antigens for a period longer than four days was selected as feasible and was tested in the following manner: The thirty different types of pneumococcus which were used for such antigens represented strains which had been received from the National Institute of Health, except types 5 and 7 which were obtained from the New York City Department of Health. The antigens were prepared from Felton broth cultures which had been incubated four or five hours at 37° Centigrade. A small loopful (28 gauge platinum loop, 1 mm. inside diameter) of each living antigen was placed on a new clean microscopic slide as in making a Neufeld preparation, and the same sized loopful of purified gastric mucin was mixed well with the antigen but confined to a small area. This was allowed to dry in the air, after which the preparations were stored in regular wooden slide boxes free from dust. Mucin was added as a protective medium for the pneumococci with the idea that the specificity of the dried organisms might be demonstrated over a longer period than otherwise. However, it was found necessary to purify the gastric mucin following the method of Chase,² since the crude product contained an amorphous material which interfered with the Neufeld test.

Similar dried preparations were made, using pneumococcus antigens types 1, 2, and 3, which had been formalinized according to the National Institute of Health requirements. In addition, four serial sets of dried living preparations not containing formalin were made for testing cross reactions of pneumococcus typing serum.

From the Bureau of Laboratories, Michigan Department of Health.
Received for publication, Nov. 9, 1946.

As shown in Table I, the thirty different types of dried pneumococcus antigens prepared with purified gastric mucin gave very good Neufeld reactions for a period of four weeks. Positive agglutination of all the different types of pneumococcus was demonstrated throughout the entire observation period of nine weeks, whereas the capsules gradually disintegrated after four weeks. The pneumococcus antigens which were formalinized, that is, types 1, 2; and 3, gave results which were comparable to those of the dried living antigens.

++, Positive agglutination and capsular swelling.

±, Positive agglutination and less than 90 per cent capsulation, with debris present.

+, Positive agglutination and no capsular swelling.

*Types 1 to 15, inclusive, prepared 4/18/39; remaining types prepared 4/19/39.

†Formalinized according to National Institute of Health requirements, prepared 4/19/39.

In order to check the efficiency and dependability of the dried antigen preparations for testing pneumococcus typing sera, four such sera were tested: first, by the method required by the National Institute of Health, and second, by the same method except for substitution of dried living antigen preparations in place of formalinized antigens in suspension. After the Neufeld tests were prepared they were incubated for one-half hour at 37° C. as required by the National Institute of Health. Upon examination the dried antigen preparations were found to be as clean-cut in appearance as were the other preparations.

In summary, the dried antigen preparations made from fresh living antigens of thirty different types of pneumococcus gave good specificity tests as determined by Neufeld reactions both for capsular swelling and agglutination for a period of four weeks. After four weeks there was a gradual disintegration of the capsules resulting in a deposit of amorphous debris in the preparations. Similarly prepared formalinized antigen preparations of types 1, 2, and 3 pneumococcus gave corresponding results over the same period.

The dried preparations proved to be equally satisfactory for testing anti-pneumococcus typing serum. The results were equivalent to the results obtained by using the same sera and following the directions given by the National Institute of Health.

Although we were not familiar with Pranion's³ improved technique for pneumococcus typing by the "Quellung" reaction when this study was in progress, it is interesting to comment in passing that the results obtained by Pranion are in agreement with the findings reported here.

It is also of interest in connection with this study to call attention to Eddy's⁴ report of a simple procedure for detecting cross reactions in diagnostic anti-pneumococcic serum.

BOOK REVIEWS

Acetanilid: A Critical Bibliographic Review. By *Martin Gross*, M.D., Research Assistant (Assistant Professor), Laboratory of Applied Physiology, Yale University; with an introduction by *Howard W. Haggard*, M.D., Director, Laboratory of Applied Physiology, Yale University. Hillhouse Press, New Haven, 1946. Price \$3.00. Cloth with 155 pages.

The content of 763 articles and textbook descriptions concerning acetanilid, a drug which is an active ingredient of many proprietary analgesic preparations, has been critically reviewed and presented in monograph form by Dr. Martin Gross. Support for this extensive bibliographic research came from the Institute for the Study of Analgesic and Sedative Drugs, which in turn derives its funds from contributions from the manufacturers of analgesic and sedative drugs. This is the first of a series of similar monographs soon to be published dealing with salicylates, phenacetin, bromides, and antipyrine.

The author has reviewed the widely scattered literature describing the first preparation of acetanilid in 1852 by Gerhart, the discovery of its antipyretic and analgesic properties by Cahn and Hepp in 1886, the ensuing years of its extensive exploitation for reducing fevers and the later development of therapeutic applications of its analgesic properties, the pharmacologic investigations of its mode of action and pathway of metabolic alteration in the body, and finally the beginning of search by David Lester (1943-1944) and others for the answers to problems described in the review. This summary serves, as Dr. Howard Haggard mentions in the foreword of the book, "to indicate the needs for more definite work on unestablished points and will lead to the avoidance of much unnecessary duplication of studies already made." Dr. Gross has included eight figures and twenty-four tables, many of which represent his own organization or graphic presentation of comparative data from the original sources.

The author's mode of handling controversial subjects is best exemplified by his treatment of the problem of the intermediary metabolism of the drug, a problem which he discusses in the light of twelve series of studies. Many widely quoted statements were found to be based on speculation. Concrete evidence was found available in the form of actual compounds identified and fragmentary evidence from studies of hypothetical substances forming methemoglobin.

In the chapter on pharmacology and toxicology, the mechanisms of and the factors affecting the formation of methemoglobin and of sulfhemoglobin are extensively discussed. It is made apparent that therapeutic doses of acetanilid produce little alteration of body functions other than those involved in analgesia and antipyresis. Many studies have been made with doses in the toxic range, and from these there has emerged no description of any characteristic effect, except for the appearance of cyanosis due to the formation of methemoglobin and sulfhemoglobin.

Despite many attempts several problems concerning acetanilid have been answered unsatisfactorily. Two problems are outstanding. No one has, as yet, adequately explained the mechanism by which it relieves pain, nor has the metabolic alteration of the drug been satisfactorily and definitely established.

Nearly one-half of the monograph is devoted to a résumé of 277 cases of acetanilid poisoning which have appeared in the literature. One-half of these cases occurred during the first ten years of its therapeutic use, a period of very extensive, often ill-directed and poorly controlled, clinical trial. At that time the drug was used mainly as an antipyretic and to a lesser extent as a local antiseptic dusting powder for abraded wounds and burns. In the last eighteen years, twenty-eight of twenty-nine cases of toxicity have resulted from the repeated and often prolonged administration of the drug. The only very characteristic sign of toxicity is cyanosis.

For those interested in the pharmacology and toxicology of analgesic drugs, this monograph will be a very useful guide and source of information.

HAROLD F. CHASE, M.D.

Early Ambulation and Related Procedures in Surgical Management. By *Daniel J. Leithauer, M.D., F.A.C.S.*, Chief of Surgery, St. Joseph Mercy Hospital, Detroit, Mich. Charles C Thomas, Publisher, Springfield, Ill., 1946. Price \$4.50. Cloth with 221 pages.

In this small monograph the history of early ambulation after operation is thoroughly but briefly discussed. The physiological justification for its use is carefully outlined, and the author's clinical results are tabulated in detail. Many photographs are presented illustrating the exact method recommended for the first termination of bed rest. The need for exercises and the importance of posture while in bed are also well emphasized and discussed.

By early ambulation the author means that the patient be made to walk within a few hours after operation, if possible, and always within the first twenty-four hours. He emphasizes this as a most important feature, particularly in order to avoid pulmonary complications and vascular accidents. The results achieved are described in considerable detail and include a great reduction in many postoperative complications and disability, a rapid restoration of the patient, and a great shortening in the length of hospital stay.

Over 2,000 operations in which early ambulation was employed form the basis of the author's clinical study. It should be noted, however, that the great majority of these operations were simple. There were only ten gastrectomies in the entire group. Although the period of hospital stay averaged just over two days in the case of appendectomy, patients who had had a gastrectomy remained fifteen days. One of the questions always raised in regard to early ambulation is the possibility that solid wound healing may be impaired thereby, particularly in the case of hernia operations. For this reason the data presented by the author on the recurrence rate following herniotomy are of special interest. In 235 patients operated upon, twelve, or 5.1 per cent, were found to have recurred "insofar as it can be determined by careful follow-up." This is not a high but still a substantial percentage. Yet it is not clear whether all of the patients operated upon were actually followed up. If not, obviously the twelve recurrences would add up to a much higher recurrence rate. The author has made a number of interesting technical observations, one of them of the effect of nylon sutures which he used in 100 patients; he found that in five of them difficulties followed, requiring removal of the sutures.

The monograph is well written and will prove of great interest to surgeons and others who have had no experience with early ambulation. It is no adverse criticism to state that the author is an enthusiast on the subject; indeed, enthusiasm is often needed to break down unjustified traditional resistance to change. On the other hand, it should be mentioned that the problem of postoperative care involves many factors other than the posture and movement of the patient. While a few of the related features have been discussed, the author did not sufficiently emphasize the obvious fact that early ambulation alone is not necessarily synonymous with a smooth postoperative convalescence. Moreover, there are certain contraindications to early rising after operation which are mentioned but insufficiently explained in merely thirteen lines of text. A lesser criticism might be the use of the term "laparotomy syndrome," inasmuch as laparotomy actually means an incision into the side of the patient. A more accurate term would have been celiotomy, but obviously this would not include such operations as herniotomy, thyroidectomy, and mastectomy.

The advantages of early termination of bed rest after operation have been repeatedly emphasized ever since they were first pointed out nearly fifty years ago, yet it is still not a universally applied principle in postoperative care. Surgeons, by clinging to past practices, frequently fail to achieve the maximum in efficient surgical convalescence. The present monograph should serve to challenge tradition and stimulate further interest in the subject, not only in surgical disease but in the therapy of any condition involving bed rest.

ROBERT ELMAN, M.D.

ANAPHYLACTIC SHOCK IN EGG-SENSITIVE INDIVIDUALS FOLLOWING VACCINATION WITH TYPHUS VACCINE

A STUDY OF THE ANTIGENIC RELATIONSHIP OF EGG AND CHICKEN MEAT ANTIGENS AND TYPHUS VACCINE

STANLEY F. HAMPTON, M.D.*
St. Louis, Mo.

SINCE the fall of 1942, typhus vaccine prepared on chick egg yolk sacs has been used rather extensively in Army personnel as an immunizing agent against epidemic typhus fever.

Sultzberger and Asher,¹ in 1942, reported three cases suggesting serum sickness syndrome including urticaria following vaccination with yellow fever vaccine, a chick embryo preparation. Swartz² reported a case of severe constitutional reaction manifested by urticaria, asthma, and collapse, immediately following an injection of yellow fever vaccine. The serum of this patient was positive in passive transfer to multiple allergens, including egg white and chicken meat as well as the typhus vaccine. Selman³ reported a case of eosinophilia of 78 per cent in the cerebrospinal fluid attributed to typhus vaccine given six days previously. Roth⁴ reported nine cases of various allergic manifestations, including urticaria, asthma, and gastrointestinal symptoms developing immediately following an injection of typhus vaccine. One of these nine case reports cited is typical of anaphylactic shock and is quite similar to the cases reported in this paper. Raynolds⁵ emphasized the value of obtaining a history of egg sensitivity in all candidates for chick embryo vaccine inoculations. Sprague and Barnard⁶ reported two cases of immediate constitutional reactions, one following an injection of yellow fever vaccine and the other following an injection of typhus vaccine.

Plotz, Coulson and Stevens, and Stull (joint investigation)⁷ by extensive and complete studies showed that vaccines prepared from embryonic tissues of developing chicks were allergenic and anaphylactogenic. Plotz⁷ found that eleven of 150 subjects injected with typhus vaccine became skin sensitive by test with the vaccine and/or extracts of egg white and egg yolk containing 0.01 mg. nitrogen per cubic centimeter. Coulson and Stevens,⁷ using the Schultz-Dale test, showed that typhus and encephalomyelitis vaccines were capable of fatally sensitizing guinea pigs and that the principal antigenic constituents of these vaccines were identifiable with antigens of egg white and egg yolk. These showed further, by precipitin tests, that 12 per cent of the protein nitrogen of typhus vaccine was attributed to crystallizable ovalbumin and concluded

From the Allergy Department, Army Air Forces Regional and Convalescent Hospital, San Antonio, Texas.

Since this paper was submitted, Rubin has reported a case of angioneurotic edema due to inoculation with typhus vaccine (*J. Allergy* 17: 21, 1946).

Received for publication, Nov. 21, 1946.

*Formerly Lieutenant Colonel, Medical Corps, Army of the United States.

from this that antigens of egg white, other than ovalbumin, were largely responsible for the sensitizing potency of the vaccine. Stull,⁷ using cross-neutralization experiments in passive transfer of egg-sensitive sera, showed the presence of egg white and egg yolk antigens in typhus vaccine in such quantities and specificity that typhus vaccine might produce dangerous systemic reactions in egg-sensitive individuals.

Since July, 1944, the immunization routine with typhus vaccine has been two injections of 1 c.c. each at an interval of seven to ten days. A total of 16,838 injections of typhus vaccine were administered to 8,419 military personnel at this post between Aug. 1, 1944, and Aug. 1, 1945. One anaphylactic reaction occurred in this group. The present article is a report of this case and an additional similar case admitted to this hospital from another Army post, following such a reaction and a study of the antigen-antibody relationship by means of neutralization in passive transfer tests (Prausnitz-Küstner reaction) of the sera of the two patients.

CASE REPORTS

CASE 1.—T. G., a 20-year-old soldier with a negative family history of allergic disease, gave a history of nausea and vomiting from ingestion of egg and chicken since infancy, the symptoms lasting thirty to sixty minutes. There was no history of diarrhea, urticaria, asthma, or rhinitis.

In December, 1944, this individual was given initial subcutaneous injections of typhus (1 c.c.) and cholera vaccines (0.5 c.c.) at another Army post. Within five minutes, he became extremely dyspneic and cyanotic and collapsed (fifteen minutes after the injection). The pulse was not perceptible and the heart sounds could not be heard. Epinephrine was administered at intervals of a few minutes for a total dosage of 1.5 cubic centimeters. Aminophyllin was administered intravenously and oxygen inhalation was given continuously for

two days. Twenty-four hours after the onset, generalized urticaria developed. All symptoms and signs subsided forty-eight hours later. The patient was admitted to this hospital for study.

Intradermal skin tests showed marked reactions (pseudopodia) with extracts of egg white, egg yolk, and chicken meat containing 100 PNU* per cubic centimeter and typhus vaccine diluted one thousand times. Tests with egg white extracts in strengths of 1 and 10 PNU per cubic centimeter showed slight and moderate reactions, respectively, without pseudopodia. Skin tests with extracts of thirty-five other common pollens, inhalants, and foods were negative. Skin tests with cholera vaccine in a 1:10 dilution was negative (immediate and delayed).

Passive transfer studies showed this patient's serum to be positive to extracts of egg white, egg yolk, chicken meat, and typhus vaccine even in 1:1000 dilution of the sera (Table I). Cross neutralization tests, using the passive transfer technique with egg and chicken antigens, are shown in Table II.

*PNU, Protein nitrogen unit, 0.00001 mg. of phosphotungstic acid precipitable nitrogen.

CASE 2.—C. J., a 23-year-old soldier with a negative family history of allergic disease, gave a lifelong history of abdominal cramps, nausea, and vomiting five to ten minutes after ingestion of egg, including food containing small quantities of egg, such as pastries, custards, and mayonnaise. During the past five years, he has had wheezing and dyspnea occasionally associated with the gastrointestinal symptoms following ingestion of egg. He could eat chicken with impunity.

In May, 1945, ten minutes after receiving subcutaneous injections of typhus (1 c.c.) and cholera (0.5 c.c.) vaccines, the patient developed a generalized tingling sensation, nausea, vomiting, and dyspnea, and collapsed in fifteen minutes. Generalized urticaria and edema of lips, eyelids, hands, and feet ensued. The radial pulse was not perceptible and the heart sounds were rapid and only faintly heard. The blood pressure was 70 to 100 systolic over 0 to 60 diastolic, the skin was cold, and the patient was in obvious shock. There were no auscultatory asthmatic signs.

Epinephrine (0.5 c.c.) was administered immediately and the patient was wrapped in blankets. Hot water bottles were applied. Five hundred cubic centimeters of blood plasma, containing 0.5 c.c. of epinephrine, were given intravenously and this was repeated. The patient's skin became warm and the severe shock subsided after 250 c.c. of plasma were administered, but the blood pressure remained low and nausea, vomiting, and abdominal pain continued for eighteen hours. The urticaria lasted two days.

A written description of this patient's experience is as follows: "I received an injection of typhus and cholera at the immunization unit on this post at 1400. After approximately ten minutes, I began to have a choking sensation in my throat and a definite wheezing in my chest. There was a tingling, stinging sensation around the hairline of my head, hands, and feet. My first thought was that I was overheated from the sun. After reaching a shady place, the reaction was no different except that I knew I was getting worse. My feet stung so badly I couldn't stand on them. I couldn't get my breath. I could feel my face and hands begin to swell. I ran to the nearest dispensary which was about two and one-half blocks away. I was having terrific abdominal cramps. I vomited three times as they put me on a stretcher and brought me to the observation ward of the hospital in an ambulance. I had to sit up to

get my breath. I fought an oxygen mask. I vomited time after time. My face, hands, and feet became swollen and my feet ached. I was still having a lot of trouble with breathing."

Intradermal skin tests showed marked reactions (pseudopodia) with extracts of egg white, egg yolk, and chicken meat containing 100 PNU per cubic centimeter and typhus vaccine diluted one hundred times. Skin tests with extracts of thirty-five common pollens, inhalants, and foods, in strength of 10,000 PNU per cubic centimeter, were negative. Skin test with cholera vaccine in 1:10 dilution was negative (immediate and delayed reactions).

Passive transfer studies showed this patient's serum to be positive to extracts of egg white, egg yolk, chicken meat, and typhus vaccine in 1:100 dilutions of the serum (Table III). Cross neutralization tests, using the passive transfer technique with extracts of egg white, egg yolk, chicken meat, and typhus vaccine, are shown in Table IV.

NEUTRALIZATION EXPERIMENTS IN PASSIVE TRANSFER

Neutralization tests in passive transfer were carried out with the sera of the two patients (Cases T. G. and C. J.) presented. Dilutions of 1:10 of each serum were prepared with normal saline. The diluted sera were mixed with equal quantities of typhus vaccine and extracts of egg white, egg yolk, and chicken meat in varying strengths. Skin sites were prepared with 0.1 c.c. of each mixture in a recipient reacting negatively to test with the most concentrated form of each material used. The serum-antigen mixture skin sites were tested forty-eight hours later with typhus vaccine and with extracts of egg white, egg yolk, and chicken meat containing 100 PNU per cubic centimeter (Tables II and IV).

The serum of one patient (T. G. Case 1) was significantly neutralized to test with typhus vaccine by extracts of egg white, only negatively by extracts of egg yolk and not at all by extract of chicken meat in the strength of extracts used. Typhus vaccine, on the other hand, neutralized completely to test with extracts of egg yolk and chicken meat but only partially to the extract of egg white. Egg white and egg yolk neutralized to test with each other only negligibly. Egg white and egg yolk completely neutralized to test with chicken meat, although it required a strength of 1,000 PNU per cubic centimeter in the case of egg yolk. Chicken meat failed to neutralize significantly to test with either egg white or egg yolk (Table II). The experiment with serum of this patient was repeated using another skin recipient, and essentially the same results were obtained.

The serum of another patient (C. J., Case 2) was significantly neutralized by the respective antigens similarly as in the case of serum of patient T. G., except that less concentration of antigens was needed to neutralize the serum (Table IV). In addition, egg yolk and chicken meat, although failing to neutralize completely to test with typhus vaccine, did show definite neutralizing qualities, more so than in the experiments with serum of patient T. G. A greater tendency toward cross neutralization by the egg white, egg yolk, and chicken meat was noted with serum of patient C. J. than with that of patient T. G. (Tables II and IV). The experiment with serum of patient C. J. was repeated twice, using different skin recipients, and essentially the same results were obtained.

The fact that each antigen neutralized to test with itself indicated that the strength of extracts used in the experiments were in proper range.

EXHAUSTION NEUTRALIZATION TESTS IN PASSIVE TRANSFER

At the time the two sera were retested in determining the quantity of skin-sensitizing antibody contained therein (the dilution at which the serum no longer reacted in passive transfer), serum sites were prepared with 1:100 and 1:1000 dilutions of each serum. It was confirmed that serum of patient T. G. was positive in the 1:1000 dilutions, whereas, serum of patient C. J. was positive in the 1:100 but negative in the 1:1000 dilutions when tested with egg white, egg yolk, chicken meat, and typhus vaccine.

These prepared serum sites were retested at one- or two-day intervals with the original testing antigen until no reaction occurred. The sites were then

1:1000	Typhus vaccine	0	Typhus vaccine	0	Typhus vaccine	0	Egg yolk	0

tested with typhus vaccine. Extracts of egg white and egg yolk were used when typhus vaccine was the original testing antigen.

In the case of serum of patient T. G., typhus vaccine induced a slightly positive reaction after the 1:100 dilution serum sites were exhausted with chicken meat and egg yolk extracts (100 PNU per cubic centimeter), respectively, but failed to do so in the 1:1000 dilution sites. The typhus vaccine reaction was questionable in the 1:100 dilution site exhausted by egg white. A slight reaction was induced by egg white in the 1:100 dilution site exhausted by typhus vaccine (Table V).

In the case of serum of patient C. J., typhus vaccine induced a questionable reaction after the 1:100 dilution serum site was exhausted with egg white extract (100 PNU per cubic centimeter). The remaining reactions were negative as shown in Table VI.

PRECIPITIN TESTS

Precipitin ring tests were carried out with the concentrated sera (Patients T. G. and C. J.) and serial dilutions of typhus vaccine from 1:2 to 1:512. No precipitins were demonstrable.

COMMENT

The case reports of anaphylactic shock following parenteral injections of typhus vaccine prepared on chick embryo yolk sacs presented and the demonstration of positive skin tests and skin sensitizing antibodies in the serum of these patients to typhus vaccine indicate that typhus vaccine may be antigenic and dangerous when injected into hypersensitive individuals.

The demonstration of positive skin tests to and skin-sensitizing antibodies in the sera of typhus vaccine-sensitive patients to egg white, egg yolk, and chicken meat suggests a close antigenic relationship between typhus vaccine and these antigens.

The cross neutralization experiments described with typhus vaccine by egg white, egg yolk, and chicken meat antigens in passive transfer studies strongly indicate the active antigenic factors in typhus vaccine to be egg white, egg yolk, and chicken meat; the egg white is probably the most important, and the latter two, respectively, are less important. This confirms the work of Stull.⁷

The exhaustion neutralization experiments further indicate that the principle antigenic factors in typhus vaccine are those of egg white, egg yolk, and chicken meat but that there may be an additional one unrelated to these antigens. If the latter is true, such antigen is probably present in minute quantity since the reactions obtained with typhus vaccine in serum sites exhausted by egg and chicken antigens were of small magnitude.

It is suggested that all candidates for injections of typhus vaccine or other chick embryo vaccines be thoroughly questioned before such injections are administered and that all probable egg sensitive individuals be skin tested intradermally with approximately 0.02 c.c. of typhus vaccine diluted with normal saline to 1:100 and, if indicated, 1:10 dilution before vaccination is instituted.

It is recommended that individuals showing positive skin reactions to typhus vaccine and other similar chick embryo vaccines be exempt from vaccination with these materials.

Whereas minor reactions not coming to the attention of the medical personnel may have occurred, the fact that only one anaphylactic reaction occurred in 8,419 individuals receiving typhus vaccine, coupled with the fact that egg sensitivity has been considered one of the most common of all food sensitivities, suggests a low incidence of food allergy in military personnel, as previously reported.⁸

SUMMARY

1. Two cases of anaphylactic shock following parenteral injections of *typhus vaccine* prepared from chick embryos infected with epidemic typhus rickettsia are reported.

2. Intradermal skin tests, passive transfer tests, and neutralization experiments with serum from the two cases presented indicated a likely antigenic identity of typhus vaccine and the egg and chicken meat antigens contained therein.

3. It is recommended that all candidates for typhus vaccine injections or other similar chick embryo vaccines be questioned for possible egg sensitivity and that all probable egg-sensitive individuals be skin tested with typhus vaccine prior to parenteral administration thereof. A suggested initial testing strength is a 1:100 dilution of the vaccine using approximately 1/50 c.c. volume. These precautionary measures have been advised by the War Department TB MED 114, Nov. 9, 1944.

4. Since *influenza virus vaccine* (types a and b) is prepared from infected chick embryos, it is suggested that the same precautions be taken with this vaccine.

Acknowledgment is made of the valuable assistance of Sergeant Jack Ladwig, Sergeant Walter Goodey, and Corporal David Mitzkus.

THE RELATIONSHIP OF GASTRIC ACIDITY TO THIAMINE EXCRETION IN THE AGED

HENRY A. RAFSKY, M.D., F.A.C.P., BERNARD NEWMAN, CH.E., M.S., AND
NORMAN JOLLIFFE, M.D., F.A.C.P.
NEW YORK, N. Y.

IN A study of the gastric secretory response in the aged, it was shown that while hyperchlorhydria was not infrequently found the majority of the subjects had 19 degrees or less of free hydrochloric acid in the gastric juice.¹ In previous articles²⁻⁴ it was also demonstrated that there is a tendency to avitaminosis in the aged. Jolliffe⁵ suggested that the failure of some elderly people to absorb thiamine may be due to the achlorhydria so frequently encountered in this age group.

The relationship between gastric acidity and secretion and thiamine has been extensively studied. Notwithstanding the numerous references on this subject, however, a difference of opinion still exists as to the effect of thiamine deficiency upon the gastric acidity and secretion. As a result of the work of Cowgill and Gilman on dogs,⁶ the prevailing opinion has been that thiamine deficiency suppresses the gastric secretion. Joffe and Jolliffe, in 1937, postulated the presence of an achlorhydria-preventive factor in the vitamin B complex, which was not identical with either vitamin B₁ or the antipellagra factor.⁷ Danysz-Miehel and Koskonski⁸ found a decrease in volume, acidity, and peptic activity of the gastric secretion elicited by histamine in a study of pigeons kept on a diet of polished rice. Gildea and associates⁹ were unable to find any change in the acidity or the pepsin concentration of the gastric secretion evoked by histamine in dogs kept on Cowgill's Casein III diet. Shay and co-workers¹⁰ recently reported their results of the effect of thiamine chloride depletion upon the spontaneous gastric secretion in rats. They found that after an acute severe thiamine depletion the volume of spontaneous gastric secretion was much greater than in their corresponding controls, while the acidity and peptic power remained normal. Elsom¹¹ kept two human beings on a diet deficient in thiamine; he found that the gastric acidity was normal after an oatmeal gruel meal in one subject and that a normal gastric secretory response to histamine was obtained in the other. Williams and associates¹² reported a low level or an absence of acidity in four young women maintained on a low thiamine diet.

In view of the differences of opinions as to the effects of thiamine deficiency upon the gastric acidity and secretion and in view of the tendency of aged individuals toward a decreased gastric acidity, as well as the prevalence of avitaminoses in elderly subjects, it was thought of interest to study the relationship between the thiamine levels and the gastric acidity in a group of apparently normal individuals 65 years of age and over.

This study was aided by a grant from Hoffmann-La Roche, Inc., Nutley, N. J.
Received for publication, Oct. 4, 1946.

EXPERIMENTAL PROCEDURE

This study is based on a series of thirty-one persons whose ages ranged from 65 to 81 years. Fourteen were men and seventeen were women. All were apparently normal individuals who were ambulatory and who were fed the routine institutional diet which was adequate in thiamine content. A chemical analysis showed that this diet contained per day from 0.51 to 1.11 mg. of thiamine, 0.97 to 1.78 mg. of riboflavin, 16.0 to 117 mg. of ascorbic acid, 2.5 to 10.0 mg. of iron, 6.9 to 13.1 mg. of nicotinic acid, 1,500 to 11,800 U. S. P. units of carotene, and from 1,300 to 5,500 U. S. P. units of vitamin A.* The results of the analyses of six separate twenty-four hour periods may be seen in Table I. The methods used for the vitamin analyses were those of Hennessey and Cerecedo¹³ for the thiamine, Rubin and co-workers¹⁴ for the ascorbic acid, the American Association of Cereal Chemists^{16a} for the iron, Krehl and associates^{16b} for the nicotinic acid, the Association of Official Agricultural Chemists¹⁷ for the carotene, and Dann and Evelyn¹⁸ for the Vitamin A.

TABLE I. VITAMIN ASSAY PER TWENTY-FOUR HOUR PERIOD

TWENTY-FOUR HOUR PERIOD	METHOD						
	B ₁ ¹³	B ₂ ¹⁴	C ¹⁵	IRON ^{16a}	NIACIN ^{16b}	CARO- TENE ¹⁷	VITAMIN A ¹⁸
First	0.88	0.97	59	5.6	11.6	6,000	2,700
Second	0.83	1.33	16	10.0	10.4	11,400	1,900
Third	1.11	1.78	117	3.7	13.1	11,800	1,900
Fourth	0.84	1.22	16	9.0	6.9	2,100	1,300
Fifth	0.70	1.29	18	2.5	8.6	8,800	1,300
Sixth	0.51	1.03	40	10.9	10.6	1,500	5,500

Results are expressed in milligrams per day, except carotene and vitamin A which are U. S. P. units per day.

The method of procedure was as follows: Twenty-four hour specimens of urine, collected under toluene and stored in the refrigerator, were analyzed for their thiamine content.¹³ An analysis of the gastric contents with the subject in the fasting state, as well as the secretory response after a water and toast test meal, was made. These determinations were done fractionally. An attempt was made to extend the analyses for one hour, but this was not always feasible in elderly subjects. If no free hydrochloric acid was found, the subjects were given an injection of histamine hydrochloride in the dosage of 0.1 mg. per 10 kilograms of body weight. These determinations were carried out for one hour.

RESULTS

In Fig. 1 there are plotted the thiamine chloride levels and the determinations of the fasting-free hydrochloric acid, and in Fig. 2 are plotted the B₁ levels when the free hydrochloric acid was at its height. The experimental data may be seen in Table II.

A thiamine excretory level below 50 μ g per day was regarded as subnormal.¹⁹

Of the thirty-one subjects studied, fourteen, or 45.1 per cent, had low hydrochloric acid values. Six had true achlorhydria, that is, no free hydro-

chloric acid was obtained after the injection of histamine. Two of the six subjects had subnormal daily urinary excretions of thiamine, and four had levels ranging from 98 to 330 μ g per day. Nineteen subjects had from 2 to 49 degrees of free hydrochloric acid, and ten of these showed abnormally low thiamine excretion values. Six of the thirty-one subjects had 50 degrees or more of free hydrochloric acid after a water and toast test meal. Two of these six subjects showed subnormal thiamine excretions. One had a free hydrochloric acid of 82 and a total acidity of 102 degrees, with a thiamine excretory level of 28 μ g per day, and the other had a free hydrochloric acid of 68 and a total acidity of 86 degrees, with a daily vitamin B₁ excretion of 66 micrograms.

DISCUSSION

As was stated before, a difference of opinion exists as to whether there is any causal relationship between gastric acidity and the thiamine status of an individual. This was of especial interest to us in view of the tendency to hypochlorhydria and avitaminoses in elderly individuals. In this study we found both high and low thiamine values in subjects with anacidity, hypochlorhydria, and hyperchlorhydria. These findings are illustrated in Fig. 2. Since a low

thiamine excretion is compatible with a histamine-fast achlorhydria as well as with a hyperchlorhydria, it is questionable whether there is any causal relationship between the gastric secretory response and thiamine deficiency in apparently normal elderly subjects. In trying to explain the low thiamine levels in the aged, several factors must be taken into account. The most important of these are inadequate intake, lack of assimilation or absorption, and improper utilization of the amount that has been absorbed. In this study the factor of inadequate intake was ruled out by careful vitamin analysis of the diet. Furthermore, as will be shown in a subsequent paper²⁰ the subjects took a sufficient amount of food which was determined by careful supervision as well as by weighing and measuring their intake. In regard to assimilation or absorption, the "conditioned malnutrition states" as described by Jolliffe⁵ were not present. It is our opinion that the tendency to avitaminosis in the aged arises from a lack of proper utilization of the amount that has been absorbed. This subject is still under investigation and will be reported in a forthcoming paper.

In appraising thiamine levels in individuals past the age of 65, another possibility must be kept in mind. The so-called normal levels of the various vitamins that have appeared in the literature are based on studies on infants, children, and young healthy adults. It is possible that these values do not apply to the age group that we have been studying. As an example of just such an occurrence, a series of studies by Newman and Gitlow^{21, 22} may be cited. These authors showed that the normal values reported in the literature for as basic a physiologic value as red cell, hemoglobin, and white cell values do not seem to be applicable to individuals past the age of 65. It is conceivable that we may be dealing with the same type of standards in the case of thiamine.

SUMMARY AND CONCLUSIONS

1. Of thirty-one elderly subjects studied, 45.1 per cent had low thiamine excretory levels.
2. The fasting gastric acidity and the secretory response after a test meal were determined in all of these subjects.
3. Both high and low excretory levels of thiamine were found in subjects with an acidity, hypochlorhydria, and hyperchlorhydria.

THE EVALUATION OF THE VITAMIN C STATUS OF HUMAN SUBJECTS: STUDIES WITH INTRADERMAL DYE DISCOLORATION, CAPILLARY FRAGILITY, FASTING PLASMA VITAMIN C LEVEL, AND VITAMIN C SATURATION

ALBERT H. HOLLAND, JR., M.D., JAMES C. CANNIFF, M.D.,
AND MAURICE BRUGER, M.D.
NEW YORK, N. Y.

THE recognition of a subclinical scorbutic state has assumed major importance in recent years. Normal or near normal concentrations of vitamin C in the tissues are necessary for the normal function of the capillary wall, for adequate wound healing and the repair of fractures, and for the normal metabolism of some amino acids. This vitamin, moreover, may play a part in specific enzyme systems and detoxification functions relative to sulfanilamide type compounds. Consequently, emphasis has been placed on various laboratory procedures which might be utilized to demonstrate vitamin C saturation or unsaturation.

In 1938 Rotter¹ described an intradermal dye discoloration test. His technique was tested extensively by a number of investigators including Portnoy and Wilkinson² and Suzuki³ who maintained that a satisfactory correlation existed between this procedure and the blood vitamin C level. Beek and Krieger⁴ found this test to agree with the results obtained by vitamin C saturation studies. In a recent paper Slobody⁵ found that the skin test denoted the degree of body saturation with vitamin C. He concluded that the discrepancy between plasma ascorbic acid levels and the results of the skin tests could be explained by the fact that the blood level at any given time reflected only the recent intake of vitamin C. This statement requires further confirmation since Slobody showed that the intravenous administration of 200 mg. of vitamin C decreased the intradermal skin test time in forty-four of forty-five cases as the plasma vitamin C level rose; this implies a reciprocal relationship between the two procedures. Goldsmith and associates⁶ concluded that no correlation existed between the plasma vitamin C level of fasting subjects and intradermal dye discoloration. Wright and MacLenathan⁷ observed that the variation in the discoloration time using Rotter's method was too great to establish a normal range; moreover, these workers showed that discoloration times varied appreciably at different body sites.

Roberts and co-workers⁸ found a close correlation between vitamin C intake and capillary fragility. They concluded that the capillary fragility test might be useful in showing relative saturation or unsaturation in given individuals or groups. Wright and Ludden⁹ observed that subjects receiving inadequate amounts of vitamin C demonstrated increased capillary fragility before the classical signs of scurvy became manifest. Abt and associates¹⁰

From the Department of Medicine, New York Post-Graduate Medical School and Hospital, Columbia University.
Received for publication, Oct. 12, 1946.

denied the existence of a significant correlation between plasma vitamin C level and petechial formation. It is now generally recognized that several clinical conditions other than scurvy (infectious disorders, acidosis, menstruation, blood dyscrasias, hypertension) as well as some toxic agents (arsphenamine, carbon monoxide) affect the strength of capillaries.

The fasting plasma vitamin C level has been widely accepted as a reliable biochemical index of the state of ascorbic acid nutrition. Farmer,¹¹ using the results of Thysell's¹² investigations, compiled a table which demonstrated the relationship between the dietary intake of vitamin C and the fasting plasma vitamin C level. Croft and Snorff¹³ studied a group of fifty healthy student nurses on a regular hospital diet. The fasting plasma vitamin C values varied from 0.60 to 1.12 mg. per cent with an average of 0.81 mg. per cent. These figures compared favorably with those of Farmer and Abt¹⁴ and of Portnoy and Wilkinson.² Kruse¹⁵ maintained that no correlation existed between the data derived by different methods of vitamin C assay in the same patient. He stated that the practice of testing the validity of a procedure by comparing its results with blood values was unsound, since blood values shift rapidly and fluctuate intermittently while tissue concentrations undergo slow change.

The vitamin C saturation test has been found to be an excellent index of ascorbic acid deficiency. Wright and co-workers^{9, 16, 17} and other investigators¹⁸⁻²⁰ have reported extensively on the various methods and procedures of vitamin C excretion tests. The former group derived a formula in which the one and one-half hour and five-hour urinary excretion of vitamin C after the intravenous administration of 1 Gm. was used to calculate the twenty-four hour saturation index. This index was shown to be more significant than the five-hour excretion value because the index nullified the factor of renal retention.

The present study was undertaken to correlate several of the more commonly employed procedures used to denote vitamin C unsaturation. This investigation embraces observations on the intradermal dye discoloration test, the capillary fragility test, the fasting plasma vitamin C level, and the vitamin C saturation test.

MATERIAL AND METHODS

Thirty-four patients admitted to the general medical service and fourteen normal volunteers (interns, nurses, and technicians) comprised the subjects used in this study. In each case the tests were run consecutively in the morning after an overnight fast. The evening meal on the day preceding the studies did not include foods rich in vitamin C. The order of testing was as follows: intradermal dye discoloration, capillary fragility, plasma vitamin C level, and the vitamin C saturation test.

The intradermal dye discoloration test was carried out simultaneously on both arms according to the procedure of Slobody.⁵ The average of the two tests was taken as the dye discoloration time. The N/300 solution of 2,6 diethylphenol-indophenol was not prepared freshly every day but was checked by titration against vitamin C for standardization twice weekly. The standards outlined by Slobody were employed. Accordingly, a dye discoloration time of more than fourteen minutes denoted a definite degree of vitamin C unsaturation, from nine to thirteen minutes mild unsaturation, and less than nine minutes a normal concentration of vitamin C in the tissues.

The capillary fragility test was performed and interpreted according to the procedure and standards outlined by Wright and Lillienfeld.²¹ Less than ten petechiae, in a circle 2.5 cm. in diameter approximately 1 inch below the crease of the elbow after fifteen minutes of tourniquet pressure halfway between systolic and diastolic blood pressure, are considered normal; ten to twenty petechiae were interpreted as border line, whereas over twenty petechiae denoted definite evidence of increased capillary fragility.

The plasma vitamin C was determined by the Farmer and Abt metaphosphoric acid method.¹⁴ The normal fasting level was considered to range from 0.6 to 1.4 mg. per 100 c.c. of plasma.

The vitamin C saturation studies* were carried out according to the procedure of Wright and Ludden.⁹ One gram of vitamin C was injected intravenously after a twelve-hour fast. Urine specimens were collected at one and one-half and five hours after the injection; the total five-hour excretion and the twenty-four hour saturation index were calculated. An excretion rate of over 450 mg. of vitamin C was considered normal for the five-hour period and over 500 mg. for the twenty-four hour saturation index.

Although Krnse¹⁵ maintained that no correlation could be expected to exist between the various laboratory procedures for determining vitamin C nutritional status, it was felt, nevertheless, that some biochemical or biophysical test which most closely approximates the clinical status must be accepted as a standard in order to compare the relative adequacy of other procedures. This is particularly true if any one method is to be used exclusively in order to determine vitamin saturation or unsaturation. In this study the five-hour excretion test was adopted empirically as the method of choice, and the other indices compared with it. The twenty-four hour saturation index was not used as a basic standard since in several instances it was impossible to calculate this value. Moreover, in only one instance (Case 17) was there any discrepancy between the five-hour excretion value and the twenty-four hour saturation index.

RESULTS

In Table I the observations made on the forty-eight cases studied are given in detail. This table was constructed according to the values obtained in the five-hour urinary excretion of vitamin C in ascending order.

This protocol reveals a lack of correlation between the intradermal dye discoloration time and the five-hour excretion of vitamin C in thirteen of the forty-eight individual tests performed (27 per cent). Only obvious discrepancies were used in these calculations since the borderline zone of nine to fourteen minutes in dye discoloration time was considered compatible with vitamin C saturation or unsaturation. The notable exceptions occurred in Cases 20 to 25, 29, 32, 34, 37, 38, 44, and 46.

Assuming the fasting vitamin C content of the plasma in nutritionally normal individuals to be at least 0.6 mg. per 100 c.c., a fair degree of correlation was noted between this index and the five-hour urinary excretion value. Obvious discrepancies were observed in seven of the forty-eight tests performed (15 per cent). The exceptions noted were in Cases 14, 17, 20, 22, 27, 34, and 37.

A marked degree of discrepancy was noted between capillary fragility and the five-hour urinary excretion of vitamin C. Here again, the borderline zone of ten to twenty petechiae was considered compatible with vitamin C saturation or unsaturation. Nevertheless, a lack of correlation between these two indices was observed in twenty-four of the forty-eight tests performed

48	26	M	Normal	1,038		10:00	1.50	50

(50 per cent). The exceptions noted were in Cases 2 to 4, 6 to 8, 11, 14, 15, 23, 26, 28, 31, 34, 37, 39, 40, and 42 to 48. It should be pointed out here that in six patients (Cases 23, 26, 28, 31, 39, and 45) the discrepancy between capillary fragility and the five-hour saturation test may be ascribed to the underlying pathologic disturbance resulting in capillary injury (rheumatic heart disease, purpura, hypertension, polycythemia vera, and thrombophlebitis). In the eighteen remaining instances in which a lack of correlation was observed between these two procedures, no obvious reason to account for the discrepancy was disclosed. In the final analysis, therefore, no correlation was observed between the capillary fragility test and the five-hour saturation test in eighteen of the forty-eight tests performed (37 per cent).

DISCUSSION

The dye discoloration test exhibited serious technical difficulties and inconsistencies aside and apart from the high degree of discrepancy when compared with the saturation test. Thus, allergic reactions, such as induration and erythema at the site of the injection, were occasionally noted; these occurred twenty-four to ninety-six hours after the administration of the dye. In one subject the local reaction was marked and accompanied by a dermatitis involving the forehead, bridge of the nose, and flexor creases of the fingers. Moreover, significant variations in dye discoloration time were observed when the test was performed simultaneously on both arms. Peculiarly enough, this phenomenon could be repeated with identical results twenty-four hours later. Again, some difficulty was experienced in reading the absolute end point of dye discoloration, and some degree of uncertainty was always present concerning the validity of an absolute intradermal injection.

The capillary fragility test was found to be nonspecific. The present meager knowledge of capillary physiology and pathology renders any procedure based on capillary rupture extremely difficult to interpret. Massive petechial formation may occur in several clinical conditions (such as, blood dyscrasias) as well as in frank scurvy. Again, fragile capillaries produced by vitamin C deficiency will not rupture under tourniquet pressure if anemia is concomitantly present presumably due to the decreased blood volume.

CONCLUSIONS

1. The vitamin C saturation test, the intradermal dye discoloration time, the fasting plasma vitamin C level, and the capillary fragility test were carried out on thirty-four patients and fourteen normal subjects.

2. Serious discrepancies between the dye discoloration test and the five-hour urinary excretion of vitamin C were observed in 27 per cent of the tests performed. Other noteworthy objections to the intradermal dye discoloration test have been described.

3. A satisfactory correlation was observed between the fasting plasma level and the five-hour urinary excretion of vitamin C. In only 15 per cent of the cases studied were exceptions noted.

4. Obvious discrepancies between the capillary fragility and the saturation tests occurred in 37 per cent of the subjects investigated.

SERUM PROTEINS IN HYPOPROTEINEMIA DUE TO NUTRITIONAL DEFICIENCY

MARTHA M. BIELER, M.A., AND ENRIQUE E. ECKER, PH.D., CLEVELAND, OHIO,
AND TOM D. SPIES, M.D., BIRMINGHAM, ALA.

THE ultimate source of all body proteins is dietary protein. Dietary protein is absorbed from the gut as amino acids, and these acids are resynthesized into the special types of body protein. Inadequate intake of protein leads to a depletion of tissue protein. A sufficiently severe depletion of tissue protein is reflected in the serum proteins because there exists, between the cellular and serum proteins, a dynamic equilibrium involving a continuous interchange of materials between the blood and the tissues. Although the serum protein level is not an absolute indication of the state of the body proteins, hypoproteinemia reflects depletion of protein in other tissues.

Blood serum contains a variety of proteins which can be classified as albumin and globulins according to physical and chemical characteristics. Each performs distinct bodily functions in addition to the all-important but little-understood relationship to tissue nutrition. Serum albumin influences the water balance of the body. The edema which is often observed in cases of severe hypoproteinemia is thought to be due to a depletion of albumin below the level necessary for maintaining adequate colloid osmotic pressure within the vascular system.

Most studies on the problem of serum protein production have been confined to the synthesis of serum albumin because a reduction in the concentration of albumin usually precedes that of the globulins. The globulins are of vital importance because of their immunologic functions. Their complexity has been shown clearly by the fundamental work of Tiselius on the separation of plasma proteins by electrophoretic analysis. By this means the globulins have been divided into alpha, beta, and gamma components, and their quantitative relationship has been determined.

On the basis of electrophoretic analysis of blood serum of patients with a great variety of diseases, certain generalizations have been made. In febrile conditions the alpha globulins are elevated. In nephrosis the beta globulins are high, possibly because of the presence of a labile lipoprotein.¹ Marked increases in the gamma component occur in rheumatic fever,² amyloidosis,²

University of Cincinnati College of Medicine Studies in Nutrition at the Hillman Hospital, Birmingham, Ala. From the Institute of Pathology, Western Reserve University, Cleveland, Ohio.

This study was made possible by grants from the Commonwealth Fund and Swift and Company.

Received for publication, Dec. 20, 1946.

relapsing malaria,³ and sarcoidosis.⁴ In certain diseases affecting the liver there is often an elevation of all three globulins.⁵ Changes in the relative distribution of these proteins during the course of many diseases bear no direct relationship to total protein level, although the total protein level is not necessarily normal.

Although hypoproteinemia may result from severe hemorrhage, burns, or disturbances of digestion, absorption, and utilization of proteins, the most common cause of hypoproteinemia is insufficient intake of dietary protein. In a large Nutrition Clinic where hundreds of patients with various forms of malnutrition are seen yearly, many patients have been observed who, for years, have existed on a low protein diet and who have serum protein level 30 to 40 per cent below the normal value. The clinical implications of this type of hypoproteinemia are not well understood. In some of the advanced cases edema may occur, suggesting a depletion of serum albumin; but other cases show no signs of edema.

Although undernutrition and malnutrition have been recognized as contributing factors in chronic infectious diseases and in susceptibility to infection, observations of certain malnourished, anemic individuals at the Nutrition Clinic have revealed such patients to be remarkably free from infection despite low serum protein levels. In order to secure further data on these cases, electrophoretic patterns of blood serum, complement and complement components, opsonic indices, and natural antibodies have been compared with those of healthy subjects and with a series of patients with various other diseases.

MATERIALS AND METHODS

Three groups of subjects were selected for study. The first group included seven adults who had no evidence of any disease or infection. They appeared to be in excellent health; their diets were adequate in all respects, and they were working every day. The second group included fourteen malnourished patients, thirteen adults and one child selected from the Nutrition Clinic and from the wards of the Jefferson Hospital. These patients had various diseases (Table I), and it was known that their diets had been inadequate in protein for at least a short time. To what extent the infection was responsible for the poor nutritional status is not known. The third group included eight adults with anemia who had been observed in the Nutrition Clinic for at least three years. Three had Addisonian pernicious anemia, one had nutritional macrocytic anemia, and four had iron deficiency anemia. All had subsisted on low protein diets for several years but were free from infection of any kind.

Fasting (overnight) samples of blood were drawn by venous puncture. The blood was allowed to clot, was centrifuged, and the serum was transferred to ampules in an ether-dry ice bath. Serum samples were preserved in the frozen state.

Electrophoretic analysis of all sera was carried out in a standard Tiselius apparatus according to Longsworth's technique.⁶ A veronal buffer, pH 8.6, ionic strength 0.1 was employed. The serum was dialyzed forty-eight hours in 2

liters of buffer; then the serum protein concentration was adjusted to 1.2 per cent by dilution with buffer. Electrophoresis was allowed to proceed for 9,300 seconds with a current of 15 milliamperes. Results were recorded photographically by the *Schlieren* scanning method.⁷ Measurements were made in terms of relative quantities (weight per cent) of albumin and alpha, beta, and gamma globulins by means of planimeter tracings of enlargements of the photographic plates. Descending patterns only were used for the calculations.

Total proteins were determined by the micro-Kjeldahl method for nitrogen. A sulfuric acid-phosphoric acid-copper sulfate digestion mixture was used, and Nessler's reagent was employed for the colorimetric estimation of the ammonia

formed. Tungstate sulfate precipitation was used in the preparation of protein-free filtrates for N.P.N. determinations.

For a qualitative study of the serum proteins, the immunologic properties of each serum were measured with respect to three well-known natural attributes of serum: complementary activity, opsonic index, and antish sheep antibody titer.

The components of hemolytic complement have been shown to be distributed among the globulin fractions of the serum proteins.⁸ Although the complementary activity of the blood determines to a large extent its immunologic properties, a deficit of any or all of the components of complement causes no obvious changes in the electrophoretic pattern of the serum since complement comprises only a small portion of the serum globulins. For this reason complement titers are included in our data. Complement determinations were carried out as soon as possible after the serum had been prepared, since complementary activity decreases gradually even when the serum is preserved in the frozen state. The serial tube method described by Ecker and associates⁹ was used. The values represent the amount of serum necessary to bring about complete hemolysis and 50 per cent hemolysis of a standard amount of sensitized sheep red blood cells. Tests for the reactivation of components were carried out for all sera. These values are reported in terms of per cent hemolysis of a given amount of sheep cells brought about by small amounts of serum to which an excess of specifically inactivated complement components were added.

The opsonic index of serum was measured by the degree of opsonization of organisms which do not undergo phagocytosis in the absence of an opsonic agent. In the absence of antibodies natural opsonins have been identified with three of the components of complement.¹⁰ They represent an important mechanism in reaction to infectious agents; therefore, measurement of opsonic indices is helpful in the evaluation of the serum globulins. Determinations were made according to the method described by Ecker and Lopez-Castro.¹⁰ All leucocytes were obtained from the venous blood of the same normal individual. The organism used was *Micrococcus candidus*.^{*} The number of cocci ingested by 100 polymorphonuclear leucocytes was counted on each slide.

In addition to the antibodies which are formed in response to invasion, human blood serum normally contains agglutinins which are generally active in low dilutions against certain cellular antigens. The antigen used in this study was the sheep erythrocyte. The sera to be tested were heated at 56° C. for ten minutes to inactivate complement. Serial tube dilutions from 1:2 to 1:128 were then made with 0.85 per cent saline in such a manner that the total volume in each tube was 0.5 cubic centimeter. A 2 per cent suspension of sheep erythrocytes was prepared from 2 cubic centimeters fresh sheep blood washed four times with saline and diluted to 100 cubic centimeters. To each tube of diluted serum and to a "blank" tube containing 0.5 cubic centimeter saline was added 0.5 cubic centimeter of this cell suspension. The tubes were shaken, incubated one

^{*}*Micrococcus candidus* was obtained through the kindness of Dr. C. A. Mills, University of Cincinnati Medical School.

hour at 37° C., and allowed to stand overnight in an icebox. Readings were made according to the size of the erythrocyte clump remaining after the tube had been tapped firmly once. The values reported represent the highest dilution of serum capable of causing definite agglutination of the sheep cells.

DATA AND RESULTS

Serum Protein Fractionation by Electrophoresis.—Electrophoretic data are presented in Table I. Typical patterns are illustrated in Fig. 1. The average values for normal controls are in agreement with the data published by other

TYPICAL ELECTROPHORETIC PATTERNS

A1b = Albumin ; α , β , and γ refer to those globulin fractions

Fig. 1.—Note similarity of the patterns for the controls *a* and *b* and the anemia patients *h*, *i*, *j*, and *k*, as compared with the differences between the patterns for the controls and the patterns for patients with various diseases *c*, *d*, *e*, *f*, and *g*.

workers¹¹ as are the data for the patients with various other diseases.^{2, 3, 5} The patterns for the patients suffering from anemia and hypoproteinemia resemble very closely the normal patterns. The only consistent variation is a slight elevation of the gamma globulins with a relative drop in either albumin or alpha globulin.

Immunologic Tests.—Contained in Table II are the results of complement titrations and reactivations, natural antish sheep antibody determinations, and opsonic indices.

Values for 50 per cent hemolysis readings in the complement titrations are within the normal range for all cases with the exception of No. 8. Reactivation tests on this serum indicate that there was a relative deficit of all complement

Complement titers, expressed as cubic centimeter serum required to bring about 50 per cent and 100 per cent hemolysis under the conditions of the titration.

Reactivation, expressed as per cent hemolysis.

Super, the supernatant after treatment of normal serum with a phosphate buffer, pH 7.4, ionic strength 0.02. This fraction lacks the C'1 component of complement.

Ppt, the precipitate after treatment of normal serum with phosphate buffer. This fraction lacks the C'2 component of complement.

Z, the fraction of normal serum remaining after treatment with zymosan. This fraction lacks the C'3 component of complement.

Opsonic index, expressed as number of organisms opsonified by 100 P₂2W/number of leucocytes containing organisms.

Natural antibodies, expressed as the highest dilution of serum containing sufficient antibodies to cause visible agglutination of sheep cells.

Tr, trace (very slight hemolysis).

Inc, incomplete (incomplete hemolysis).

components. Reactivation tests on the other sera showed no significant variations in strength of components, as was to be expected, since over-all complement titers were within the normal range.

The antish sheep hemagglutinin titers were somewhat lower for the deficient patients than for either group of controls. However, the ranges of values overlapped widely, and small numerical variations are within the range of experimental error.

In most cases the opsonic index counts showed 90 to 100 per cent of the polymorphonuclear leucocytes to be filled with organisms and the total number of organisms engulfed to be 500 to 1,500. In Case 28 this value was substantially lowered, indicating the absence of adequate quantities of opsonins in this serum. "Blank" controls showed not more than 10 per cent active leucocytes and not more than twenty-five organisms engulfed.

COMMENT

The data presented indicate that the blood sera of eight persons who are hypoproteinemic but have no known infection vary but slightly from the sera of healthy, well-nourished individuals with respect to distribution of serum protein fractions, complement titers, opsonic indices, and antish sheep hemagglutinin titers.

The relative decrease of serum albumin and relative elevation of serum globulin fractions in the sera of most of the hypoproteinemic patients are an indication that hypoproteinemia develops at greater expense to serum albumin than to serum globulin. However, the average deviation of the albumin:globulin ratio from the normal is extremely small as compared with the wide deviations and inversions of the ratio found in the sera of patients with other diseases. This fact suggests that in prolonged malnutrition a gradual depletion of all serum proteins occurs, since the ultimate source of all body proteins is dietary protein. Whereas, in disease increased amounts of specialized globulins may be produced, in dietary deficiency all types of serum protein may be produced in normal quantitative proportions.

Although complement titer is known to undergo extreme variations in the course of certain infectious diseases¹² the titers for all but one case studied here remained normal. Case 8 (J. T.) was the only patient who was acutely ill at the time when the blood sample was taken. Apparently the components of complement are maintained at a normal level even when other protein levels decrease. Similarly the normal opsonic index values found for deficient patients suggests such a condition, since three components of complement (C'1, C'2, C'4) together may operate as an opsonin. The variation of the natural antish sheep antibody titers between the controls and the deficient patients is of questionable significance. Thus, the results of three immunologic reactions show that the sera of persons who are hypoproteinemic but have no infection can maintain certain immunologic functions even though a rather large proportion of the total serum protein has disappeared.

Reports concerning the relationship between nutritional status and resistance to infection are at great variance. In the case of hypoproteinemia due to acute starvation, hemorrhage, or surgical operation, resistance to infection is greatly lowered, and direct loss of antibody protein is probably the contributing factor. Apparently malnutrition presents a different problem, for many malnourished patients with anemia who appear to be as resistant to certain diseases as well-nourished individuals have been observed in the Nutrition Clinic. A partial explanation has been found in the increased phagocytic activity of the neutrophils in patients with anemia.¹³ A complement to this explanation may be found in the results of the present study; that is, that in persons where hypoproteinemia exists because of a lack of materials with which to manufacture serum proteins, the limited amount of materials available contributes to the production of certain important immunologic elements.

SUMMARY AND CONCLUSIONS

1. Various characteristics of the serum proteins of twenty-nine individuals have been studied. Seven were from apparently normal, healthy adults; fourteen were from hospital patients with various diseases; and eight were from patients with hypoproteinemia associated with nutritional anemia but showing no evidence of infection.

2. Electrophoretic analysis demonstrated that the sera of the healthy individuals compare closely with the normal values recorded by other investigators. The sera of the patients with various diseases showed the abnormalities usually observed in those diseases, while the sera of the patients with anemia and hypoproteinemia differed from the normal only by a slight relative decrease in the amount of albumin present.

3. Complement titers, opsonic indices, and antishoop hemagglutinin titers of all sera showed no significant variation from the established normal values.

4. The gradual depletion of serum protein levels which follows chronic, uncomplicated malnutrition is probably a relative depletion of all types of protein distinguishable by electrophoretic analysis. Certain portions of the globulins appear to be maintained. This fact may afford a partial explanation of the resistance to infection shown by some persons who are hypoproteinemic because of dietary deficiency.

FOLIC ACID IN THE TREATMENT OF APLASTIC ANEMIA

BENJAMIN R. GENDEL, M.D.*

MEMPHIS, TENN.

MANY authors^{1, 2} have shown the value of folic acid in the treatment of pernicious anemia and a variety of other macrocytic anemias. However, reports on the use of folic acid in the treatment of aplastic, hypoplastic, or refractory anemias have shown disappointing results. Watson and co-workers³ reported their results with folic acid in the treatment of refractory anemia. They treated seven patients using 2.5 mg. twice daily for six days, and at the end of that time no beneficial effect was observed. Spies¹ found folic acid administration to be without effect on either the clinical or hematologic picture of three patients with aplastic anemia. Doan⁴ also reported negative results in six patients with hypoplastic anemia. The dosage used and the duration of treatment were not described. Zuelzer,⁵ discussing the beneficial effect of folic acid in macrocytic anemia of infancy, mentioned negative results obtained in three children with aplastic or hypoplastic anemia. Goldsmith⁶ has recently reported on the treatment with folic acid of two patients with aplastic anemia. One patient, a 51-year-old colored man, received 5 mg. and later 30 mg. of *Lactobacillus casei* factor daily. At the end of one month there had been no improvement and it was necessary to administer several blood transfusions. The second patient, an 8-year-old white boy, received 20 mg. of *L. casei* factor parenterally for ten days and then 40 mg. daily for a similar period. There was no change in the blood picture. On the other hand, in 1944 Sharp and associates⁷ reported on the treatment of ten patients with refractory anemia who were given small daily doses of Vitamin B₁₂ (0.6 to 1.5 mg.). After a month there was an appreciable increase in the hematocrit but otherwise only slight changes, and the experiment was discontinued. Recently Davidson and Girdwood⁸ have reported some beneficial effect following folic acid administration in the treatment of three patients with refractory megaloblastic anemia in whom adequate therapy with parenteral concentrated liver was ineffectual. Since folic acid has not seemed to have any therapeutic value in the treatment of aplastic anemia according to the experience of most authors, it would seem of value to record our experiences with the use of folic acid in which the apparent results of treatment have seemed a little more hopeful.

In the summer of 1945 we were faced with the problem of a patient severely ill with aplastic anemia who was having frequent transfusion reactions. This patient had already received over seventy blood transfusions in the preceding eight months and required about 500 c.c. of whole blood weekly in order to maintain a red count of 2.5 million. There had been a history of sulfonamide treatment; therefore, at the suggestion of Dr. Louis K. Diamond of Boston, we decided to observe the effects of folic acid in the treatment of this condition

From the Medical Service, Lovell General Hospital, Fort Devens, Mass.
Received for publication, Nov. 4, 1946.

*Formerly Major, Medical Corps, Army of the United States.

Later, when more folic acid was made available, two other patients were treated; this report summarizes the effect of this treatment and discusses the pertinent experimental data.

CASE REPORTS

CASE 1.—A 29-year-old white man, a lieutenant in the Air Corps, was well until December, 1944, when he developed a sore throat and fever while on shipboard en route to the United States. He was admitted to the sick bay, and a right tonsillar ulcer was found with regional cervical lymph node enlargement. A smear was reported positive for Vincent's infection, and he was treated with sulfadiazine orally, a single 0.6 Gm. injection of neonsphenamine intravenously, and neosphenamine in glycerin topically. The patient received a total of 7 Gm. of sulfadiazine by Dec. 4, 1944, when, because of continued illness, a blood count was taken; the count revealed: hemoglobin, 7.6 Gm.; red blood cells, 2,700,000 per cubic millimeter; white blood cells, 2,150 per cubic millimeter; neutrophils, 19 per cent. Medication was discontinued. On Dec. 7, 1944, a sternal marrow aspiration was done and revealed an aplasia of all cellular elements. Petechiae developed. Treatment consisted of repeated blood transfusions, penicillin, and pentnucleotide injections with some improvement. The patient received sixteen transfusions until his admission to Lovell General Hospital on Dec. 20, 1944. On admission the patient was still severely ill and was complaining of sore throat, weakness, and rectal pain.

Past History.—There was a history of atabrine ingestion of 0.1 Gm. daily for several months after April, 1944. Sulfadiazine had been administered on many previous occasions for repeated upper respiratory infections, and in addition, sulfadiazine ointment had been used freely for various cuts and abrasions during the preceding year.

Physical Examination.—A moderate pallor and a periumbilical scaly eruption were present. There were no enlarged lymph nodes and the liver and spleen were not palpable. Multiple anal fissures were present. The remainder of the examination was not significant. No petechiae or ecchymoses were noted on admission.

Laboratory Data.—In Fig. 1 are summarized the blood counts taken during the patient's hospital stay. The initial marked increase in red cell count and hemoglobin found at this hospital was attributed to the large number of transfusions given in the short time prior to admission. Sternal puncture on Dec. 29, 1944, revealed a hypoplastic marrow with a depression of the erythroid and myeloid elements and an absence of megakaryocytes.

Course.—The patient was severely ill during most of the hospital stay which lasted fifteen months. He developed petechiae, ecchymoses, epistaxis, and a hematoma of the eyelid on various occasions. In January, 1945, ulceration of the mucous membranes of the mouth was noted. In May, 1945, the patient developed a hemorrhage into the right middle ear. During hospitalization he received penicillin for intercurrent infections and over seventy blood transfusions, from one to three weekly until August, 1945. During July and August, 1945, transfusions were accompanied by a febrile and constitutional reaction but no hemolytic reaction. Careful examination for abnormal agglutinins was done and none were found. (This examination was performed by Dr. L. K. Diamond at the Blood Grouping Laboratory, Boston, Mass.) Because of the frequency of transfusion reactions and the progressive fall in the blood without them, it was decided to institute therapy with folic acid* and to try to discontinue transfusions. In August, 1945, all transfusions were stopped and none were given subsequently. Administration of folic acid, 4 mg. daily, was started. There was no reticulocytosis and no improvement in the blood picture, but the count did not drop and folic acid was continued. On Oct. 18, 1945, the dosage of folic acid was increased to 30 mg. daily and on December 6, 1945, to 200 mg. daily. During this time the red count slowly improved, although the leucocyte and platelet counts were essentially unchanged. In February, 1946, the dosage was increased to 400 mg. daily for two weeks and then was reduced to 150 mg.

*Folic acid used in all three cases in the present study was synthetic *L. casei* factor (pteroylglutamic acid) and was given by mouth.

daily. Folic acid was discontinued in April, 1946. In May, 1946, a blood count revealed: hemoglobin, 13.8 Gm.; red cells, 4,000,000; white cells, 4,000; neutrophils, 28 per cent; platelets, 54,000. The patient felt well and was ambulatory.

Fig. 1.—Summary of hematologic data in Case 1.

CASE 2.—A 32-year-old white man, a staff sergeant, developed dizziness, weakness, and shortness of breath in February, 1945. Shortly thereafter he noticed persistent headaches and in March, 1945, developed blurring of vision which progressed to temporary loss of vision in the left eye. He was hospitalized for these complaints in April, 1945.

Past History.—The patient received four sulfadiazine tablets on two or three occasions in August, 1944, because of an epidemic of meningitis in the camp at which he was stationed. Again, prior to going overseas in December, 1944, he was given several tablets of sulfadiazine for an unknown reason. There was no other history of exposure to toxic chemicals.

Fig. 2.—Summary of hematologic data in Case 2.

Physical Examination.—Hemorrhages were noted in the fundi, more marked in the left eye. A moderate pallor was present. There was no lymph node enlargement and liver and spleen were not palpable. There were no other significant physical findings.

Laboratory Data.—In Fig. 2 are summarized the blood counts taken during the patient's hospital stay. In June, 1945, a sternal marrow aspiration revealed a hyperplasia of the normoblastic and myeloid elements and a normal number of megakaryocytes. Gastric analysis revealed 42 units of free HCl after the administration of histamine.

Course.—The patient was given four blood transfusions and evacuated to the United States. Subsequently, he received transfusions about once a week from June until September, 1945. In early September, 1945, he developed abdominal pain, slight fever of 100 to 101° F., tenderness of the liver, and an icterus index of 20. There was no increase in anemia nor any other evidences of a hemolytic crisis. The condition persisted for ten days and returned to normal. It was believed that the patient suffered a mild episode of homologous serum jaundice, induced by a previous transfusion. On Oct. 13, 1945, transfusions were discontinued and the patient was started on 30 mg. of folic acid per day. This was continued until Dec. 6, 1945, when the dosage was increased to 200 mg. daily. On Jan. 1, 1946, the dosage was decreased to a maintenance dose of 15 mg. daily which was continued until February, 1946. On this regime the blood count fluctuated at about the previous levels, although the patient did not receive any of the blood transfusions which were previously necessary to maintain the blood count. No data are available concerning the further course.

CASE 3.—A 25-year-old white man, a technician fifth grade, was well until the middle of June, 1945. At that time he noted the gradual onset of fatigue. Shortly thereafter he developed shortness of breath and anorexia. On July 15, 1945, he fainted and consequently was hospitalized.

Past History.—The patient served overseas in the Southwest Pacific Theater of Operations for twenty-six months. The diet was considered adequate, and there were no gastrointestinal complaints until the patient developed anorexia two weeks prior to hospitalization. Atabrine, 0.1 Gm. five times weekly, was administered during the entire stay overseas.

Physical Examination.—A marked pallor was noted. There was a symmetrical pinkish scaling involving the chest, abdomen, and neck. Bluish bands were noted under the finger- and toenails. There was also a bluish discoloration of the skin under the eyes and over the right shin. A slight generalized lymph node enlargement was noted and liver and spleen were not palpable. The remainder of the examination was noncontributory.

Laboratory Data.—In Fig. 3 are summarized the blood counts taken during the patient's hospital stay. Fragility test was normal, icterus index was 5, and urinary urobilinogen was positive in 1:20. Stools were negative for occult blood. Gastric analysis revealed the presence of free HCl. Kahn was negative. A trephine biopsy of the sternum revealed a hypoplastic marrow.

Course.—The patient received fourteen blood transfusions of 500 c.c. each during July and August, 1945. This produced an improvement in the general condition and blood picture. The leucocytes and platelets became essentially normal, but the red cell count was fixed between 2.5 and 3.5 million. This persisted from September until December, 1945, without significant change, despite the administration of iron and parenteral liver. On Dec. 6, 1945, the administration of 200 mg. of folic acid (50 mg. four times daily) was begun. This was continued until Dec. 21, 1945, when the drug was discontinued. On this regime a progressive rise in the red count to normal was noted without any significant increase in reticulocyte count. After discharge from the hospital, a follow-up letter was received from the patient stating that he was enjoying good health and that the blood count on July 3, 1946, was normal.

DISCUSSION

The condition presented by these three patients was classified as aplastic anemia. Two of our patients (Cases 1 and 3) had a bone marrow which revealed a hypoplasia of the blood-forming elements. This, together with the peripheral blood picture of pancytopenia, would satisfy even the most rigid diagnostic criteria for this disorder. However, our second patient (Case 2) differed in that the marrow was slightly hyperplastic. The precise classification of this

type of anemia is obscure, although many authorities include them with the aplastic anemias.^{9, 10} It is for this reason, and as a matter of convenience, that our three cases are considered together.

Fig. 3.—Summary of hematologic data in Case 3.

It was extremely difficult to evaluate the etiologic factors in the pathogenesis of the aplastic anemia in these patients. In our first patient there was a history of ingestion of a number of different medications. Atabrine was

taken for suppression of malaria during the summer months. However, it is unlikely that it was related to the development of the aplastic anemia, because such cases were not seen in patients from the Mediterranean Theater of Operations where atabrine was taken only for a few months during the year. There was also a history of the administration of 7.0 Gm. of sulfadiazine in about two days. On numerous previous occasions our first patient had taken sulfadiazine for a variety of infections and had abundant opportunity to develop a drug sensitivity. In addition, he also received an intravenous injection of 0.6 Gm. of neocarsphenamine and neocarsphenamine in glycerin was applied topically to the tonsillar ulcer. Whether or not these drugs given singly or combined were responsible for this condition cannot be stated with any degree of certainty. There is a strong possibility that the patient may have had an aplastic anemia from the onset and that the tonsillar ulcer was a manifestation of this disease. Unfortunately, no blood counts were obtained until after the drugs were administered, when it was obvious that the patient was not improving.

The second patient also had a history of sulfadiazine ingestion, but the latent period was too long before the onset of symptoms for one to consider it seriously as a causative factor. The third patient gave a history of prolonged ingestion of atabrine while overseas in the Southwest Pacific Theater of Operations. He also showed the lesions of atypical lichen planus which are currently believed to result from atabrine toxicity.¹¹ Some patients with atypical lichen planus have also developed visceral damage including aplastic anemia.^{11, 12} It is possible but not certain that atabrine played some role in the development of the condition of our third patient.

The rationale for the trial of folic acid in the treatment of aplastic anemia was based on the experimental production of anemia, leucopenia, and granulocytopenia in rats on sulfonamide therapy. This peripheral blood picture was similar to the pancytopenia of aplastic anemia. In addition, it has been shown that folic acid deficiency in rats was accompanied by a progressive hypoplasia of the marrow with a depletion of all the marrow elements.¹³ In extreme cases aplasia of the marrow was produced. Thus, it is seen that, experimentally in rats, deficiency of folic acid produces an aplastic anemia.

The results obtained in these three patients were not as striking as the improvement shown by folic acid-deficient rats in which there was a return to a normal blood picture after four days of treatment. In macrocytic anemias the results are also more striking, and a reticulocyte response may be demonstrated similar to the one obtained from adequate liver therapy. No significant reticulocytosis was manifest in any of these patients. In our first patient we were having difficulty with transfusions which he required at least once a week in order to maintain a satisfactory blood count. He showed a gradual improvement in the red count, which rose to better levels than we could maintain on transfusions. Improvement was such that he was transformed from a bedridden patient to one who was ambulatory and capable of ordinary activity. However, a complete remission had not been attained, as evidenced chiefly by the continued low platelet count and also by the persistent leucopenia and

granulocytopenia. In our second patient we were able to dispense with transfusions, although the count did not rise to better levels. The third patient already had had a partial remission, as evidenced by a normal sternal marrow aspiration, normal white count and differential, and normal platelet count prior to starting therapy with folie acid. The red count remained low after several months of observation and did not rise after attempts at therapy with iron and liver extract. Following the administration of folie acid, the patient had a remission which he has maintained for eight months after the completion of treatment.

It is realized that the improvement of these three patients may very well be a coincidental spontaneous remission, and there is evidence in our third patient that a remission had started before folie acid was administered. However, it is possible that folie acid may have had some beneficial effects on the course of the disease, and it is believed that a trial of folie acid using large doses over a long period of time is justified.

CONCLUSIONS

1. Three patients with aplastic anemia were treated with folie acid.
2. Treatment was associated with a remission of varying degree in each instance.
3. It is recommended that large doses used over a long period of time be given a trial in the treatment of this condition.

APLASTIC ANEMIA FOLLOWING ADMINISTRATION OF THOROTRAST

JACK SPIER, M.D.,*† LEIGHTON E. CLUFF, B.S.,* AND WILLIAM D. URRY, PH.D.‡
WASHINGTON, D. C.

SINCE thorium dioxide has come to be used extensively as a diagnostic test for visualization of the liver, spleen, placenta, ureter, kidney pelvis, and certain blood vessels,²¹ it is important to record in the literature any toxic reactions which seem to have occurred as a result of the thorium administration. We have recently had an opportunity to study a patient with hypoplastic anemia who had been given thorium dioxide in usual diagnostic amounts nine years previous to the development of the hypoplastic anemia; there were presumptive reasons for thinking that the thorium might possibly have caused the hypoplasia.

Reports have appeared in the literature which indicate that thorium dioxide (thorotrast) might have late toxic manifestations of a serious nature. This toxicity may present itself with irritative or destructive effects, primarily on reticulo-endothelial and hematopoietic tissues; however, other tissues are involved, such as the kidney, where a nephritis has been produced experimentally.^{12, 15} Martland and associates,^{2, 3, 10} Gettler and Norris,⁴ Sabin and co-workers,¹¹ and Foulds¹⁴ have observed the development of osteogenic sarcoma clinically and experimentally from the use of radioactive materials, principally radium, although thorium is seen to produce similar effects. Efsskind¹⁵ produced papillomatous growths by the intraperitoneal injection of thorium. These same investigators, in addition to Lambin and Gérard,⁷ Gottlieb,⁶ and Meakins,⁵ have demonstrated aplastic anemia or hypoplastic anemia with destruction and hypoplasia of hematopoietic tissue following thorium administration. The sarcomatous changes usually develop later than the aplastic anemia, the sarcoma developing between ten to twenty years and the aplastic anemia developing five to ten years after the administration of the radioactive material.⁹

Martland and associates^{2, 3, 10} further state that thorium is a more active disrupter of blood centers than radium. Investigators are cognizant that a patient may remain in good health for many years before toxic manifestations appear. Descriptions of such cases in the literature, however, are not numerous, and not all observers are in agreement that the amounts of thorium used clinically may be injurious.^{6, 8} The case presented here serves further to illustrate the evolution of an aplastic anemia following the use of radioactive thorium.

CASE REPORT

A 53-year-old colored woman was admitted to the hospital Oct. 7, 1944, with a chief complaint of fever and persistent headache.

One week before entry the patient noted onset of a persistent headache. Accompanying the headache there developed fever and dizziness. Shortly before this there had been some anorexia and weight loss. The severity of these symptoms had increased progressively up to the time of admission. The family history was essentially negative. The patient had been in an automobile accident twenty-two years prior to admission, after which a left hemiplegia was present with left ear deafness and paralysis of cranial nerves VI and VII. She had typhoid fever in childhood and nine years before hospitalization was studied for abdominal pain, at which time liver visualization with thorotrast was done. We are unable to find from the record how much thorotrast was given, but there is no reason to suspect that it had been more than the standard dose. A diagnosis of peptic ulcer was eventually made and a gastroenterostomy was performed. The patient's discomfort then disappeared. The catamenia was negative.

In the isolation department on admission, a negative spinal fluid was obtained. On physical examination the temperature was 99.5° F., pulse 116 per minute, respiratory rate 25 per minute, and blood pressure 114/50. The patient appeared acutely ill. The mucous membranes were pale. Two large, firm nodules, 3 cm. in diameter, were found, one in each antecubital fossa. There was a left-sided hemiplegia. The fundus of each eye showed marked A-V nicking and silver wire arteries. A small area of ulceration was found in the right tonsillar fossa. The thyroid was somewhat enlarged and nodular, and the neck veins were distended. Dullness and increased breath sounds were found in the middle one-third of the left lung area. The heart was markedly enlarged, the apex being in the sixth interspace, 12 cm. from the midsternal line, and a loud, harsh systolic murmur was heard over the apex and entire precordium. The abdomen and the pelvis revealed no abnormal physical signs.

Laboratory Data.—

Blood findings on Oct. 8, 1944, were: hemoglobin, 3.0 Gm. per 100 c.c.; red blood cells, 1.26 million per cubic millimeter (hypochromic, poikilocytic, and anisocytic); white blood cells, 450 to 950; hematocrit cell volume, 8 per cent; differential—lymphocytes, 88 per cent, neutrophils, 2, bands, 1, juveniles, 8, basophils, 1.

Blood findings on Oct. 10, 1944, were: red blood cells, 1.25 million; white blood cells, 210; hemoglobin, 4.1 grams.

Urinalysis on Oct. 9, 1944, revealed: specific gravity, 1.010; albumin, trace.

On Oct. 9, 1944, a sternal marrow study showed marked reduction in all nucleated elements as well as platelets. A blood culture was negative at this time.

On Oct. 10, 1944, an x-ray revealed a small contracted spleen and negative chest. On Oct. 11, 1944, blood cultures showed large gram-negative rods; additional cultures of blood revealed similar growths. On Oct. 12, 1944, a positive agglutination was obtained with Friedländer's bacillus Group A serum. The organism was nonencapsulated. The patient died on this day.

There was nothing in the patient's history to indicate that she ever had been exposed to any hematopoietic toxin other than thorium dioxide.

Necropsy.—The body was that of a well-developed somewhat emaciated colored woman. A few pigmented areas were seen over the anterior aspect of both lower extremities. A well-healed linear scar was found in the upper right abdominal quadrant. There was no cyanosis, edema, jaundice, or lymph node enlargement. Pin-point petechiae were present over the chest. No free fluid was found in the peritoneal or pleural cavities. There were adhesions between the abdominal scar and the transverse mesocolon. The liver extended 3 cm. below the right costal margin and the spleen was very small. The apex of the left lung was bound by stringy fibrous adhesions to the parietal pleura. The heart weighed 320 grams and was flabby in consistency. There was no hypertrophy or dilatation of the chambers and the valves were negative. The coronary vessels were patent and showed only an occasional atheromatous plaque. The lungs together weighed 800 grams and were

edematous and congested, the left lower lobe showing some bronchopneumonia. The liver weighed 1,400 grams and was congested with slight peripheral "nutmegging." Fifteen to twenty pea-sized, dark green calculi were found in the gall bladder; these were soft and friable. The spleen weighed 15 grams, had a wrinkled thickened capsule, was rubbery in consistency, and on section showed a delicate grayish white dense framework. The pancreas and adrenals were negative. The kidneys together weighed 250 grams. Their capsules stripped easily and showed pale red surfaces. The corticomedullary ratios and demarcations were not disturbed. A slight white grayish streaking was present in the cortices. The pelvis showed pin-point hemorrhages. The uterus had a pedunculated fibromyoma, 2 cm. in diameter, and the left ovary contained a hazelnut-sized cyst. A few hemorrhagic areas were seen in the stomach and the large bowel on their mucosal surfaces. A rubbery blood clot, which was firmly attached to a hemorrhagic area, was found in the peripyloric region. The thyroid was enlarged and nodular. Nodules were seen which were encapsulated; some had undergone cystic degeneration. The bone showed osteoporotic trabeculae and pale gray somewhat moist marrow.

Fig. 1—Thorotrast in splenic pulp (histiocytes).

Fig. 2.—Thorotrast in bone marrow cells.

Histopathology.—The section of uterus shows a typical fibromyoma. There is lipomatosis and congestion of the pancreas. Tubular degeneration and desquamation of the kidney with vasculization of the glomeruli and beginning nephrosclerosis is found. Scattered necrotic areas surrounded by lymphocytes are in the liver; there are however, no giant cells. Around these areas and about the central veins and portal fields is a grayish dark translucent pigment. Pigment is also seen in hepatic and Kupffer cells. There is widening of trabeculae in the spleen and marked fibrosis of the pulp. Large amounts of grayish dark translucent pigment are present in the pulp and capsule (Fig. 1).

The splenic capsule is thickened and fibrotic. The lung tissues show focal areas of emphysema and other areas of focal fibrosis and congestion. The adrenals are partly autolyzed. A mediastinal lymph node contains caseous necrosis and foci of fibrosis and

congestion. A grayish dark translucent pigment is seen here also which does not appear to be anthracotic. The ovary shows focal fibrosis. The heart shows myocardial fragmentation. The bone marrow is aplastic and contains dark gray translucent pigment (Fig. 2).

Radioactivity.—The radioactivity of samples of the bone marrow and spleen were determined by one of us (W.D.U.). This was accomplished with a special design of Geiger-Mueller counter in such a way as to afford comparisons with standard preparations of thorium by the alpha particle plus beta ray count and independently by the gamma ray count.

In addition to these two methods of making the comparison, the tissues were examined in two states. For the preliminary measurements the formalin was removed and the tissues were dried and powdered. For the final determinations the powdered tissues were ignited at 800° C., leaving only the inorganic oxides of the radioactive and other materials. In Table I under the fifth column is shown a good agreement between the content of thorium oxide determined on the dried tissue and on the ignited residues. In Table I also is demonstrated an abnormally high content of inorganic material (7.9 per cent by weight) in the bone marrow, not all of which is thorium oxide as shown in the sixth column of the table.

TABLE I. CONTENT OF THORIUM OXIDE BY WEIGHT IN TWO TISSUES FOLLOWING ADMINISTRATION OF THOROTRAST

TISSUE	STATE OF SAMPLE	PER CENT OF THORIUM OXIDE IN SAMPLE	PER CENT OF SAMPLE IN ORIGINAL TISSUE	PER CENT OF THORIUM OXIDE IN ORIGINAL TISSUE	PER CENT OF ALL OTHER INORGANIC OXIDES IN ORIGINAL TISSUE
Bone marrow	Dried	23.0	22.10	5.10	3.10
	Ignited	60.0	7.90	4.80	
Spleen	Dried	1.2	23.20	0.28	0.34
	Ignited	42.0	0.59	0.25	

Thorium, like uranium, is the progenitor of an established series of a number of radio elements. Radium is but one of these elements in the uranium series. The radioactivity of a sample of thorium arises largely from the disintegration of a succession of radio elements each derived in turn from its preceding parent. In old preparations, such as the standards used here, equilibrium will have been established and the average number of disintegrations in a given time will be the same for all the members. This is not true if the preparation has been disturbed chemically, but it is unfortunate that, from the viewpoint of the clinical use of thorotrast, the radioactivity of a preparation of thorium can never be reduced below about one-half of the maximum because an important member of the series (namely, radiothorium) is chemically identical with thorium itself (an isotope).

A comparison of the gamma ray measurements and the alpha particle plus beta ray determinations on the tissues in this case indicated that the thorium oxide had been undisturbed chemically for about nine years. This calculation was performed without knowledge of the case history, and it is a gratifying

TABLE II. DENSITY OF RADIATION IN TWO TISSUES EXPRESSED AS TOTAL EMISSION OF EACH TYPE OF RAY PER MINUTE PER GRAM OF TISSUE IN FORMALIN STATE

TYPE OF RADIATION	BONE MARROW	SPLEEN
Alpha particles	43,300	2,200
Beta rays	25,800	1,300
Gamma rays (primary)	28,000	1,400

confirmation of the measurements to note that administration of the thorotrast occurred 10.2 years before the date of the radioactive determinations.

The density of the radiation to which the tissue was being subjected was calculated for the three types of radiation from the data in Table I and the known radioactive constants for the elements in the thorium series, taking into account the state of radioactive equilibrium after nine years. The results are given in Table II.

Not all the rays of a given type in Table II possess equal energies. In studies of the pathologic effects of radiation a definite physical unit for the energy generated should be employed. Such a unit is the ergs per hour per gram of dry tissue. For the thorium series, after nine years, the energy per thorium alpha particle plus that of the alpha particles and beta rays from the decay products is 44×10^{-6} erg. The energy derived from the gamma rays is negligible and in any case is not dissipated locally as will be discussed. On this basis the thorium oxide in 1 Gm. of dried bone marrow produced 123 ergs per hour and 1 Gm. of dried spleen 6.3 ergs per hour. Some of this energy may be lost to the tissue by exhalation through the lungs of the sixth element in the series which is a gas (namely, thoron); however, according to measurements on the exhalation of radon,¹ an isotope of thoron, there could not be more than a 40 per cent reduction in the energy of radiation received by the tissue.

According to the literature^{10, 23} numerous examples of acute symptoms have been observed, where the dosage of radiation energy in the body tissues, for comparable lengths of time, was even less than in the spleen in this case.

Radiation from thorium: Thorium dioxide, the agent used in this case for diagnostic purposes, is usually marketed as thorotrast, a colloidal sol of thorium dioxide (25 per cent). As far as radioactivity is concerned, there is no difference, except for the numerical values of the radioactive constants, between thorium and the members of its series and uranium and its members, one of which is radium. Both series emit all of the same three types of rays, alpha particles, beta rays, and gamma rays. The alpha particle is a positively charged nucleus of a helium atom and possesses comparatively great kinetic energy by virtue of its mass and high velocity of 12 to 18 thousand miles per second. However, this energy is completely dissipated in a very short distance, not more than a few tens of microns in tissue. Beta rays consist of electrons of much smaller mass but greater velocities approaching that of the speed of light. Their maximum energy is on the average about $\frac{1}{10}$ of that of the alpha particles, but some travel up to $\frac{1}{2}$ mm. in tissue before this energy is completely dissipated. Gamma rays are quanta of energy, similar in all respects to x-rays except for the much higher frequency of vibration. They travel with the speed of light and most of them possess sufficient energy to pass completely through the human body. The bio-

logic effects of alpha, beta, and gamma rays are said to be correlated in the following numerical values: 10,000, 100, and 1, respectively.

It is important to realize from what has just been said that there is a very great difference between the external and internal application of one and the same source of radiation in the type and degree of radiation to which the parts of the body may be subjected. The human body can be subjected without harm to surprisingly large quantities of radiating material placed in its immediate vicinity for short periods of time; time is an important element. The reasons for this are: (1) gamma rays are the only ones which effectively enter the body tissues on external radiation (except in the case of proximity to a cyclotron or fission process when a large and hazardous dose of neutrons may be experienced in addition to gamma radiation), and (2) the body receives only that part of the radiation within the solid angle subtended with the source. The same quantities administered internally have often proved fatal.

In internal administration of material such as thorium, whose decay products emit all three types of rays, the toxic effects within the body tissues are due almost entirely to alpha particles. The action of the gamma rays is negligible, and by comparison with the effects of the alpha particles, the action of the beta rays can be dismissed as minimal.

THE DISTRIBUTION AND ACTION OF ADMINISTERED THORIUM

The distribution of thorium is dependent upon the route of administration. Following intravenous injection it is first taken up by capillary endothelium and then phagocytized by the cells of the reticulo-endothelial and hematopoietic systems, including liver, spleen, bone marrow, lymph nodes, lungs, gonads, suprarenals, and placenta, but it is not transmitted to fetus.^{3, 8, 20-22}

The excretion of the thorium is comparatively rapid from the liver and spleen; however, its diminution from bone marrow is extended over a long period of time, portions of the administered material remaining indefinitely in the marrow. Following disintegration of the thorium into its corresponding series of elements, thoron, a gaseous radio element, is eliminated by the lungs. Partial excretion of the thorium dioxide takes place through the kidneys.^{3, 8, 9, 16, 21}

In the liver the Kupffer cells and hepatic cells are seen to hold quantities of thorium, while the monocyte cells and sinusoidal spaces of the spleen contain thorium after its administration.^{3, 8, 9, 16, 20-22}

The irritative and destructive effects with concomitant fibroblastic proliferation and regenerative hyperplasia result in replacement of normal tissues, as well as causing cell maturation arrest and interference with nuclear mitosis. Subsequently abnormal cellular elements appear.^{3, 20}

The grayish dark translucent pigment found in the bone marrow, liver, spleen, and lymph nodes corresponds to the usual classical pathologic description of thorotrast in the tissues. This histopathologic observation, as well as the studies of the radioactivity, demonstrates the presence of thorium in this case. The mechanism of the development of aplastic anemia is well confirmed

in the literature as arising from the radiation of hematopoietic tissues, and it may be presumed that such a mechanism was operative in this case.

The problem remains to establish an explanation for the fact that many patients suffer no harmful effects following the use of radioactive material. We cannot offer an explanation other than that which is discussed by others, namely, that there is an individual susceptibility to the radiation. However, we do propose that, besides individual susceptibility, there may be differences in the mode and speed of excretion in different persons which cause retention of more radioactive material in some than in others.

SUMMARY AND CONCLUSIONS

The existence of an aplastic anemia in our case is established beyond doubt. Measurements of radioactivity in the formalin-fixed tissues verify with equal certainty the presence of radioactive material in the body. In addition, histopathologic appearance of liver, spleen, and bone marrow sections reveals a grayish black diffusely distributed pigment within the sections, which according to present knowledge could be diagnosed only as being thorotrast. An attempt has been made to deduce that the radiations arising from the thorium series of radio elements could have been responsible for the aplastic anemia and fatality.

The literature concerning the toxicity of radioactive materials is reviewed so as to demonstrate the actual occurrence of untoward effects. Also, a brief résumé of the action of thorium in the body is undertaken in the hope that it may clarify the actual participation of radioactive agents in pathologic changes in the body tissues.

STUDIES ON LEUCOCYTE GRANULES AFTER STAINING WITH SUDAN BLACK B AND MAY-GRÜNWARD GIEMSA

RALPH N. BAILLIF, PH.D., AND CECIL KIMBROUGH, R.T.
NEW ORLEANS, LA.

IN MANY types of clinical and investigative work, it frequently becomes necessary to locate lipids in tissues. Several types of dye can be used for this purpose but those of the sudan series, particularly sudan III and IV, have become especially popular. When frozen sections (or other materials which have not been subjected to the action of fat solvents) are stained with a solution of one of these dyes, the lipid inclusions are specifically reddened. The density and shade with which these inclusions are colored depend somewhat on the technique, the chemical nature of the lipid, and the particular lot of dye. About a decade ago Lison¹ discovered that still another member of this dye family, sudan black B, can be successfully employed as a histologic lipid stain. After treatment with a solution of this stain, lipid inclusions are specifically blackened.

In his original paper Lison¹ discusses in detail some of the technical problems associated with the use of red dyes. He notes that when inclusions are stained in red (that is, with sudan III or IV) there is no common cytoplasmic dye which brings them into satisfactory contrast. If the inclusions are large and/or numerous, lack of sharp contrast is not particularly detrimental; should they be small and few, however, this factor adds to the difficulty of locating and studying them under the microscope. Optical differentiation, the author points out, is greatly improved by use of sudan black B, for the blackened lipid masses are sharply contrasted by any of the common cytoplasmic stains.

Sudan black B has been used not only on tissue sections but also for staining of bacterial films (Hartman² and Burdon and associates³) and blood films (Sheehan⁴). We shall be particularly concerned with the latter type of preparation in the present investigations.

In his rather brief report Sheehan⁴ has noted that definitive granules of both mature and immature leucocytes are blackened by exposure to sudan black B, while other parts of these cells are unaffected. With his technique, granules of eosinophile leucocytes, for example, appear to stain only on their surfaces, giving one the impression that they are hollow in nature. This author has found also that some myeloblasts contain sudanophilic granules while others are entirely sudanophobic in reaction.

The foregoing method for staining leucocyte granules is, however, of limited usefulness because of the difficulty of accurately identifying the cells concerned. This is especially true of immature leucocytes where finer details of cytoarchitecture and tinctorial reaction are prime criteria for differentiation of cell types.

From the Department of Anatomy, Louisiana State University School of Medicine.
Received for publication, Nov. 8, 1945.

It is often found that the dye combinations commonly used for staining blood films are not entirely adequate for study and differentiation of various granular inclusions in leucocytes. For this reason an attempt was made to devise a combined technique, wherein a well-standardized method (May-Grünwald Giemsa) was used to bring out the main structural features of leucocytes and a relatively new dye (sudan black B) to stain their granular inclusions. It will be shown later that this combined technique retains most of the advantages of the May-Grünwald Giemsa method and at the same time brings out granule morphology especially well.

In testing this new method, paired films of normal and pathologic blood were made; one member of each pair was stained with May-Grünwald Giemsa and the other with the sudan May-Grünwald Giemsa combination. Comparisons then were made on leucocytes in the two types of preparation, and an attempt was made to determine the effects of the sudan stain. Later, some films were stained with sudan alone (as suggested by Sheehan) and used to check the findings. By these methods we were able to note that certain features of leucocyte morphology can be most profitably studied only after preparation of films by the combined technique.

MATERIALS AND METHODS

After a number of trials it was found that dried blood films can be advantageously studied after fixation in formalin-alcohol and staining with sudan black B and May-Grünwald Giemsa. These films were treated in the following manner:

1. Fix thoroughly dried (preferably for twenty-four hours) blood films for five seconds in a mixture of:

Formalin	10%
95% ethyl alcohol	90%

2. Wash in distilled water and dry.

3. Stain with sudan black B solution at room temperature for one-half to one hour. The solution is prepared as follows:

- Sudan black B powder* to saturation in 70 per cent ethyl alcohol.
- Preferably allow the solution to stand at least twenty-four hours before using.
- If a darker staining is desired, the process can be carried out at 37° Centigrade.

4. Stain with May-Grünwald Giemsa in the following manner:

- Flood the slide with the May-Grünwald mixture and allow to stand for three minutes. This procedure appears to lend greater sharpness and clarity to the Giemsa stain.
- Cover the slide with neutral distilled water and allow to stand for one minute.
- Drain without washing.

*National Aniline Division, Allied Chemical & Dye Corporation, New York, N. Y.

- d. Cover with dilute Giemsa mixture (one drop of stock solution to 1 c.c. of water) and allow to stand for ten to fifteen minutes.
- e. Wash in distilled water and dry.

This procedure gives a preparation in which erythrocytes are stained slate gray to black. As Sheehan has already noted, these structures are markedly distorted when fixation is omitted but are well preserved when it is used. We believe that leucocytes are also more faithfully preserved after initial fixation. Since no new structural features of erythrocytes are brought out by the sudan technique, they will not be considered further at this time.

Two main sources were used in securing blood for the subsequent studies:

1. Repeated films were made from blood of five normal individuals. These films were usually stained alternately, one with May-Grünwald Giemsa and one with sudan May-Grünwald Giemsa, and the two types of preparation compared by successive studies under the microscope.

2. Films were also prepared from several types of blood dyscrasias*:

- a. Two cases of secondary anemia.
- b. Two cases of pernicious anemia.
- c. Three cases of acute lymphatic leucemia.
- d. One case of chronic lymphatic leucemia.
- e. Five cases of acute myelogenous leucemia.
- f. Three cases of chronic myelogenous leucemia.
- g. Three cases of acute infectious mononucleosis.
- h. Two cases of pneumonia with eosinophilia.

In using the previously mentioned preparations, no attempt was made at a pathologic study per se, but special attention was directed toward identification of individual leucocytes and examination of their granular content.

OBSERVATIONS AND DISCUSSION

Studies on Normal Blood.—When one examines blood films stained by sudan black B only, he encounters occasional groups of sharply blackened granules; only by markedly decreasing the field illumination can he determine that these bodies are actually enclosed by the cytoplasm of otherwise unstained granulocytes. Despite the difficulty of using such films, they are sometimes valuable as an aid in examination of individual granules since they are there exposed in maximum contrast, that is, black against a tan, yellow, or colorless background. In this type of preparation one finds that the stained inclusions differ with respect to size, shape, stainability, and distribution in various leucocytes and that these differences are characteristic for the granulocyte cell types.

Successive examinations of May-Grünwald Giemsa and sudan May-Grünwald Giemsa-stained blood films indicate that the two types of preparations differ only with respect to the granular content of their leucocytes. Preliminary fixation and staining with sudan in no wise affect the tinctorial properties of

*These slides were furnished through the courtesy of Dr. Philip Pizzolato, Department of Pathology, Charity Hospital of Louisiana, New Orleans, La., and the late Dr. C. A. Stewart, Department of Pediatrics, Louisiana State University School of Medicine, New Orleans, La. The diagnoses were made by Dr. Pizzolato.

other cell constituents. For this reason it is possible to use nuclear architecture and color reaction as an aid in identifying various cells. Again, all cytoplasmic granules of nonspecific nature are unaltered by exposure to the sudan dye.

After preparation of a normal blood film by the sudan May-Grünwald Giemsa technique, *neutrophile* granules are well preserved and clearly demarcated from the surrounding cytoplasm. Under these conditions they appear to be of constant size and tinctorial properties, staining slate gray. Any apparent variability in size or color is due to the fact that they tend to collect in groups within the cytoplasm, and the observer is sometimes forced to examine the elements in superimposed state. Such granular complexes may have irregular margins and deeply staining centers. When the granules are isolated within the cell, however, each is spherical in form and sharply demarcated from surrounding cytoplasm.

The total number of neutrophile granules per cell varies considerably even under normal conditions. This variability cannot be correlated with any feature such as the number of nuclear lobes or total cell diameter. When few in number, the granules tend to collect in a zone adjacent to the centrosphere, leaving the cytoplasmic periphery relatively clear. As their number increases more are crowded toward the cytoplasmic membrane. Grouping of individual elements may be encountered in any part of the cytoplasm.

Granules of normal *eosinophile* leucocytes are well demonstrated in sudan May-Grünwald Giemsa-stained blood films. It is common to find eosinophile granules so crowded in the cytoplasm that one is sometimes forced to search for an isolated element. Under favorable conditions, however, each granule is found to consist of a deeply blackened shell and a clear, unstained core. There is a sharp line of demarcation between the two regions. In eosinophiles which have been deeply stained by the acidophilic components of the May-Grünwald and Giemsa mixtures, the sudanophobic cores are pink in color.

The granules of a majority of normal eosinophiles are spherical in form. In a few instances, however, they are shaped into oblate spheroids or plump spindles. This corroborates the findings of Downey⁵ and others for corresponding granules in animal leucocytes. Either type of adspherical granule has a sudanophilic shell of rather constant thickness and a sudanophobic core whose form simulates that of the granule as a whole. Especially in spindle-shaped forms there is a marked condensation of sudanophilic material in the poles of the granule; these densely blackened regions gradually merge with the remaining portions of the shell.

Basophile leucocytes from normal blood are difficult to study because of their scarcity, but at least one was eventually located in each prepared film. The mast granules appear to be morphologically and tinctorially identical in sudan May-Grünwald Giemsa and May-Grünwald Giemsa-prepared films. As is well known, these metachromatic bodies are colored deeply purple or purplish black with the usual hematologic stain combinations. Since this color is not strikingly different from the gray or blue black imparted to most leucocyte inclusions after exposure to sudan black B, one at first hesitates to state that mast

granules are entirely sudanophobic. Careful studies have been made on films stained with the sudan alone, however, and no basophile granules appear there in stained condition. We shall have occasion to consider them again in our studies of pathologic blood (*vide infra*).

Agranulocytes (lymphocytes of all sizes and monocytes) are readily found in normal blood films prepared by the sudan May-Grünwald Giemsa technique. These cells are identical in all particulars with those seen in preparations stained with May-Grünwald Giemsa alone, that is, they are quite unaffected by exposure to sudan black B.

In any adequately stained preparation of normal blood, one is frequently able to find azurophilic granules in both monocytes and lymphocytes. As is well known, these inclusion bodies show considerable variability in size, many ranging downward to the lower limits of microscopic visibility. With the usual hematologic dye combinations they stain in color values from brick red to reddish violet. Exposure to sudan black B appears to alter their tinctorial properties but little. It is possible that they become darker in tone, but this change is not of sufficient degree to preclude the possibility of subjective error.

Studies on Abnormal Blood.—No concerted attempt was made in these studies to differentiate the various blood dyscrasias; attention was primarily centered on cell identification and on examination of the cytoplasmic granules in various immature and pathologic leucocytes.

Blood films from several types of *secondary anemia* were studied both after staining by the May-Grünwald Giemsa and sudan May-Grünwald Giemsa techniques. In general, no strikingly new features in their leucocyte granules were revealed by exposure to the sudan stain. In one case there were numerous well-marked toxic neutrophils whose granules were large and unusually basophilic in reaction. These granules were readily identified in the sudan preparations as discrete, densely blackened bodies. It will be remembered that normal neutrophilic granules are expected to be slate gray after staining with this dye; thus, toxic alterations in the granules are reflected by an increase in their sudanophilic power.

In all cases of *pernicious anemia* followed in these investigations, it was possible to identify at least a few of the so-called "pernicious anemia neutrophilic leucocytes." Their granules are larger than those of normal polymorphonuclear cells and tend to be more acidophilic in reaction. Treatment of these blood films with sudan black B reveals that the pernicious anemia neutrophilic granules are but lightly sudanophilic, staining a light gray. Despite this mild chromatophilia, however, they are well demarcated and sharply outlined in the surrounding cytoplasm.

Blood films from four *lymphatic leukemia* cases were carefully studied in an effort to identify accurately as many of the leucocytes as possible. It was found that in both acute and chronic lymphatic leukemia none of the markedly abnormal leucocytes were sudanophilic. Especially in the acute form there appeared greatly increased numbers of lymphocytes and lymphocytoid cells. Some of these pathologic elements have basophilic cytoplasm and large, pale nuclei whose chromatin is laid down in a rather sievelike pattern. Nucleoli may or

may not be present. Comparison of May-Grünwald Giemsa and sudan May-Grünwald Giemsa-stained slides from these cases reveals no differences in the previously mentioned cells. A small number of them are granulated to some degree. The inclusions are irregular in size, distribution, and tinctorial properties, but in all instances they are quite unaffected by exposure to sudan. At least some of these pathologic lymphocytes can be identified as frank stem cells, and it is interesting to note that in our preparations they are invariably sudan-free.

The leucocytes from eight cases of *myelogenous leucemia* showed marked variability of reaction to sudan black B stain. As was found in our lymphatic leucemia studies, none of the stem cells contained sudanophilic granules (Fig. 1); with few possible exceptions, the leucoblasts were also sudan-free. On the other hand, promyelocytes of both the neutrophilic and eosinophilic series were noted to contain sudanophilic bodies in considerable numbers (Fig. 2).

Fig. 1.—Blood film from a case of *myelogenous leucemia*. The cell on the left is an eosinophilic metamyeloblast. The cell on the right is a late stem cell. The metamyeloblast contains sharply defined eosinophilic granules which stain with the sudan.

The cell on the right is a late stem cell. The stem cell contains no granules.

The cells shown in Figs. 1 to 6 were found in blood films which had been fixed in formalin-alcohol and stained with Sudan May-Grünwald Giemsa. All are magnified 1640X.

Early neutrophilic myelocytes have highly variable numbers of cytoplasmic granules but in all cases are somewhat sudanophilic from the time of their inception. During maturation through the myelocyte and metamyelocyte stages of development, these bodies increase but little in size although their staining power is considerably augmented (Fig. 3). As early as in the myelocyte form, some of the granules appear as slate-gray spheres, but the majority do not stain in this manner until almost complete maturation has been accomplished. Especially in myelocytes one first notes that these granules tend to collect in groups.

Promyelocytes of the eosinophile series likewise contain sudanophilic granules. From the time of their formation many are notably larger in size than their neutrophilic counterparts and can be differentiated from them on this basis alone. With maturation the eosinophile granules become progressively more stainable, but the chromatophilia is confined to their peripheries. In most myelocyte and in a few promyelocyte granules, one can make out the darkly staining shells and nonstaining cores. The sudanophilia of these shells continues to increase until full maturation of the cell has been completed (Fig. 4).

Fig. 2.—In this figure are shown a number of cell types in a film from a case of acute myelogenous leucemia in extremis. At the extreme right is a stem cell; its cytoplasm contains no sudanophilic granules. At the left is a late leucoblast or early promyelocyte, probably of the neutrophilic series. This latter cell is surrounded by a number of promyelocytes and myelocytes of variable size. Note in these cells that the developing definitive granules are densely sudanophilic. The intercellular debris is composed chiefly of cell fragments.

Immature leucocytes of the basophile series are identifiable in films from our cases of myelogenous leucemia. Repeated studies have led us to the conclusion that their granules are never sudanophilic at any stage of development. The mast promyelocyte typically contains granules which stain in some value of gray, both in the May-Grünwald Giemsa and sudan May-Grünwald Giemsa-stained preparations. One might consider that this shade is due to slight sudanophilia, but comparison of the two preparation types fails to show that exposure to sudan causes any change in their tinctorial properties. For this reason we believe that they are stained only by the secondary dye mixture. Progressive basophilia and metachromasia were noted as these granules appear in more mature forms.

One of the cases of myelogenous leucemia deserves special mention in that the first films of the patient's blood were taken when he appeared at the hospital in a sudden clinical crisis. At the time of admission the blood count indicated 125,000 leucocytes per cubic millimeter; a few of these were stem cells and leuco-

blasts. Promyelocytes, myelocytes, and metamyelocytes were numerous and easily identified. During the course of hospitalization, the initially high leucocyte count rapidly subsided and accompanying cytologic changes could be followed from the blood films.

Fig. 3.—A late metamyelocyte of the neutrophil series from a case of chronic myelogenous leucemia. Note the small size of the individual granules and that in some places granules are collected into groups.

Fig. 4.—A large eosinophil from a case of acute myelogenous leucemia. This cell is almost mature and has numerous well-differentiated cytoplasmic granules. Each granule is composed of a deeply blackened shell and an unstained core region.

As the crisis period neared its close, the great majority of pathologic leucocytes became involved in a degenerative process which culminated in their destruction and disappearance. This process was characterized by nuclear pye-

nosis and cytoplasmic fragmentation. Within a period of about two weeks' time, the patient's blood picture had returned almost to normal and he was discharged from the institution. Periodic re-examinations of the blood revealed a slow but progressive increase in the number of circulating leucocytes and a rise in the number of immature elements.

During the recovery phase briefly described, granules in the degenerating leucocytes showed marked changes in their sudanophilic power. It appears that the advent of cytologic disintegration is accompanied by loss of sudanophilia in such manner that the granules disappear while the cells are still superficially intact. This same process can be seen occasionally in isolated cells from nearly all leucemic blood.

Fig. 5.

Fig. 6.

Fig. 5.—An eosinophile taken from a case of pneumonia with eosinophilia of unknown etiology. In this instance the definitive granules are neither sharply demarcated nor densely sudanophilic. Many of the granules do not clearly show the core and shell regions.

Fig. 6.—A monocytoid lymphocyte from a case of infectious mononucleosis in the acute phase. Note in the cytoplasm that there are several colorless vacuoles and various granules of inconstant size. These granules are entirely sudanophobic in reaction.

Two cases of *pneumonia with eosinophilia* of unknown etiology were examined in this series. The circulating eosinophiles were, respectively, 18 and 26 per cent of the total white count. Sudan May-Grünwald Giemsa-stained blood films revealed that many of these eosinophiles were markedly abnormal in that they contained many imperfectly formed grayish granules (Fig. 5). In these bodies the shell and core regions were frequently undemonstrable in that the entire granule was weakly and diffusely stained. A few granules appeared to attain full maturity as expressed by normal tinctorial properties.

Blood films obtained from three cases of *acute infectious mononucleosis* in the acute phase were alternately stained by sudan May-Grünwald Giemsa and May-Grünwald Giemsa techniques. As is well known, there is still some doubt as to the identity of certain mononuclear cells which appear in the circulating blood during this disease. Many investigators such as Downey and Stasney⁶ now believe that these elements are pathologically modified lymphocytes. In our preparations we were readily able to find the coarse chromatin strands and

masses within their nuclei and to note that these structures were not sharply demarcated from the parachromatin substance. These features have been emphasized already by the previously mentioned authors. The cytoplasm of the pathologic lymphocytes was typically basophilic in reaction, sometimes markedly so, and occasionally contained colorless vacuoles (Fig. 6).

In a few instances the abnormal cells in these cases of acute infectious mononucleosis were noted to contain cytoplasmic granules of considerable size and number. With the usual hematologic stains, these bodies superficially resemble immature neutrophile or even eosinophile granules. Exposure of such cells to sudan black B does not alter their appearance in any respect, that is, they are entirely sudanophobic in reaction. It now seems probable that they are derived from granules of the azurophile series.

From the preceding discussion it can be seen that sudanophilia occurs in many of the same leucocyte forms which are known to have positive oxidase and peroxidase reactions. Despite the many studies on these leucocytic enzymes, there is still considerable divergence of opinion as to the significance of their presence (see Michels⁷). Notwithstanding, many investigators still follow the concept of Naegeli⁸ who believed that leucocytes of myeloid and lymphoid origins could be differentiated on the basis of the foregoing reactions. He held that myeloid leucocytes are oxidase and peroxidase positive while those of lymphatic origin are oxidase and peroxidase negative. The same general principle has been applied to immature forms, even to those as far back as the stem-cell stage.

Other investigators such as Weil and Isch-Wall,⁹ in contrast, have been unable to determine that oxidase and peroxidase reactions are consistently positive in myeloblasts. Due to the scarcity of stem cells in some bone marrows, much of this investigation has been carried out on pathologic blood. For this reason it is frequently assumed that when these reactions are negative in cells of myeloid origin, the responses are prevented by pathologic changes in the affected cells.

We have stained films of leucemic blood by the methods of Goodpasture¹⁰ and Graham¹¹ for peroxidase and by the method of Schultze¹² for oxidase. In these preparations we have studied the immature leucocytes in detail and then compared them with corresponding forms stained with sudan May-Grünwald Giemsa and May-Grünwald Giemsa methods. By these comparisons we have found that, with one possible exception, oxidase- and peroxidase-positive granules are consistently sudanophilic. This exception concerns inclusions in stem cells. It is not uncommon, for example, to find peroxidase granules in what appear to be frank stem cells. These granules tend to be irregular in size and variably stained; as such, they might be considered as artifacts formed by precipitation of the dye. The most successful sudan May-Grünwald Giemsa-stained preparations, on the other hand, are precipitate-free, and any stem cells contained therein are also free of blackened granules. From these observations it would seem that the so-called oxidase- and peroxidase-positive granules are not always sudanophilic; there is still some doubt, however, as to interpretation of the oxidase and peroxidase positive reaction.

With the possible exception of those in the myeloblast, all leucocyte granules which are consistently oxidase and peroxidase positive are also sudanophilic and stain blue black or black. Because of the high degree of contrast so effected, the granules can be more easily studied. Again, the sudan-in-alcohol solution is stable over considerable periods of time; this makes frequent solution preparation unnecessary. For these reasons it is believed that the sudan May-Grünwald Giemsa technique may be profitably substituted for various oxidase and peroxidase staining methods.

Especially in three of our cases of myelogenous leucemia there were found considerable numbers of atypical granules in the various immature leucocytes. After preparation with May-Grünwald Giemsa, these granules are amphophilic in reaction and stain reddish blue or reddish violet. On the basis of their tinctorial reaction, then, they may be considered as modified azurophilic granules. In films stained with sudan May-Grünwald Giemsa, they are readily identified as bodies identical with those previously described, both as to size and color. This means that the granules in question are entirely sudanophobic. They may be found in medium and large lymphocytes, monocytes, and occasionally in granulocytes as well. Most of them are smaller in size than definitive leucocyte granules, and some are so small as to approach the lower limits of microscopic visibility. Due to the fact that with one exception, the basophile, definitive granules are consistently sudanophilic and nonspecific granules sudanophobic in reaction, the sudan technique should prove useful in differentiating the two types of inclusions in leucocytes.

As far as is now known, sudan black B is a lipid-specific stain. If this is true, definitive neutrophile and eosinophile granules have a lipid component which appears at their inception and is progressively augmented during their maturation. It is possible that all these granules do not contain exactly the same lipid substance, since some (that is, neutrophile granules) are stained in slate gray while others (eosinophile granules) are deeply blackened. The function of the lipid component is still entirely unknown, but it is invariably found in the normal definitive granule. Pathologic forms, on the other hand, are to some extent deficient in lipid content, either in quantity or in distribution within the granule.

SUMMARY AND CONCLUSIONS

Dried films of normal and abnormal blood were stained with sudan black B and then treated with the May-Grünwald Giemsa dye combination. The first stain was found to blacken specifically the definitive neutrophile and eosinophile leucocyte granules and to leave all other cell parts unaffected. Architectural features of these cells, such as nuclear pattern, can be stained by a proved method (May-Grünwald Giemsa) and used as an aid in cell identification. Similarly, the hyaloplasm is also differentially colored so that it serves as an efficient contrast medium for the blackened granules.

After exposure to the sudan stain, neutrophile granules appear as small, spherical slate-gray bodies. They are typically collected into groups within the cytoplasm.

Eosinophile granules are larger in size than the preceding type and are spherical or spheroidal in form. They are composed of a peripheral, deeply sudanophilic shell and a central sudanophobic core. These two regions are sharply demarcated from each other.

Basophile granules are found to be sudanophobic in reaction, as are also azurophilic elements.

The granular content of some immature pathologic leucocytes is discussed briefly, especially with reference to the acquisition of sudanophilia during maturation.

Several types of abnormal granules (from pathologic blood) are considered. It is noted that sudan black B is useful in differentiating certain specific (sudanophilic) from nonspecific (sudanophobic) granules, especially when the two forms stain similarly with the usual hematologic dye mixtures.

A STUDY OF THE STERNAL MARROW AND PERIPHERAL BLOOD OF FIFTY-FIVE PATIENTS WITH PLASMA CELL MYELOMA

L. W. DIGGS, M.D., AND MARJORIE S. SIRRIDGE, M.D.
CLEVELAND, OHIO

PLASMA cell myeloma is a chronic progressive disease which is characterized by multiple osteolytic plasma cell tumors of bone and diffuse proliferation of plasma cells within the marrow. The malignant cells have a predilection for the bones which are most active in blood cell formation, such as the sternum, ribs, vertebral bodies, bones of shoulder girdle and pelvis, skull, and upper ends of the femora and humeri. Infiltration of plasma cells takes place early in the course of the disease, and aspiration of material from the sternal marrow usually reveals significant changes.

It is the purpose of this paper to summarize the cytologic characteristics of the bone marrow and peripheral blood in plasma cell myeloma, as revealed in the published literature and in marrow and blood films of fifty-five patients with the disease observed at Cleveland Clinic. The diagnosis was established by combined clinical, laboratory, radiologic, and marrow findings. Patients with unsatisfactory marrow preparations, with inadequate follow-up, and in whom the diagnosis was doubtful were excluded. Patients with an increase in plasma cells in the peripheral blood (plasma cell leukemia) also were included in the series.

The sternal marrow was collected by biopsy from one patient and from the others by inserting a needle into the marrow space, aspirating from 0.1 to 0.2 c.c. of fluid and making films directly, using the coverslip technique. The preparations were stained with Wright's stain.

BONE MARROW

The literature relating to the plasma cell has been well summarized by Maximow¹ and Michels,² as have the essential clinical and pathologic features of plasma cell myeloma by Geschiekter and Copeland.³ Descriptions of the bone marrow films in plasma cell myeloma and the value of the procedure in diagnosis and differential diagnosis have been presented by Vogel and associates,⁴ Rosenthal and Vogel,⁵ Scott,⁶ Weil and Perlès,⁷ Doan,⁸ Haden and Rumsey,⁹ Beizer and co-workers,¹⁰ and others.

The number of plasma cells in bone marrow preparations from patients with plasma cell myeloma is variable. This is explained by the fact that the tumors tend to be patchy in distribution and there are varying degrees of dilution with peripheral blood. The sternal marrow films occasionally fail to reveal an increase in plasma cells,¹⁰ but in the majority of cases there is a significant increase. The percentage of plasma cells in the bone marrow films of our series was

From the Department of Clinical Pathology, Hematology Laboratory, Cleveland Clinic Foundation.

Received for publication, Dec. 23, 1946.

determined in each patient by noting the number while making a differential count of 300 or more nucleated cells. The lowest percentage of plasma cells was 4 and the highest 90. The percentage of plasma cells was greater than 10 in forty-eight of the cases. The frequency distribution of cases according to the percentage of plasma cells is given in Fig. 1. In one patient with plasmocytoma of the clavicle, not included in this series, the percentage of plasma cells was 3.

In normal bone marrow plasma cells are always demonstrable, but their number is less than 1 per cent. In 322 unselected bone marrow films from patients with a clinical diagnosis other than plasma cell myeloma, the plasma cells were less than 1 per cent in 129 cases and less than 4 per cent in 315.

Fig. 1.—Frequency distribution of the percentage of plasma cells in the bone marrow from fifty-five patients with plasma cell myeloma.

In seven patients the number varied between 4 and 9 per cent. In three of these the diagnosis was not definitely established, and the possibility of plasma cell myeloma was not excluded. The final diagnoses in the other four patients were carcinoma, agranulocytosis, aplastic anemia, and hypochromic anemia due to bleeding fibroids. Plasma cell increase in the bone marrow has been described in chronic infections, metastatic malignancy, Hodgkin's disease, the leucemias, agranulocytosis, and aplastic anemia.

An analysis of our patients with plasma cell myeloma did not reveal any significant correlation between the percentage of plasma cells in the marrow and the duration of symptoms, the degree of anemia, the number of plasma cells in the peripheral blood, or the number of grams of total protein or globulin in the blood serum. Films with the higher percentages of plasma cells tended to have more cytoplasmic debris, but this likewise varied in different patients and in different slides from the same patient.

Plasma cells of all stages of maturation from the earliest undifferentiated cells to the more mature forms were encountered. The cells were classified on

the basis of nuclear, nucleolar, and cytoplasmic characteristics into plasmoblasts, early plasma cells, and mature plasma cells (Fig. 2).

The plasmoblast has the characteristics of other primitive cells. This cell is larger than the mature plasma cell and has a relatively large round nucleus and a light blue, unevenly staining cytoplasm. The nucleus is round and has a delicate chromatin pattern and one to four nucleoli. The nucleus tends to be eccentric; the nucleolus is usually single, very large, and well defined. The cytoplasmic margin is often irregular, and transition forms can be found between this cell and the typical plasma cells.

The early or intermediate plasma cell has a less distinct nucleolus than the plasmoblast, the nuclear chromatin is more compact, the cytoplasm stains a darker blue, the perinuclear clear zone is more distinct, and the amount of cytoplasm in relation to the nucleus is greater. The cytoplasm stains unevenly and the shape is irregular.

Fig 2—A, Plasmoblast; B, Early plasma cell; C, Mature plasma cell.

The mature plasma cells seen in plasma cell myeloma resemble those seen in normal bone marrow and in numerous other conditions. The cell is usually oval and is slightly larger than the neutrophilic leucocyte. The nucleus is relatively small, eccentric, round, and has a pachychromatic structure. The so-called cart wheel nucleus, which is often described as being typical of this cell in tissue sections, is seldom seen in dried blood films stained with Wright's stain. There is a prominent, relatively unstained area near the nucleus. The cytoplasm stains an intense blue and often has a greenish cast. In some of the cells the cytoplasm may stain so darkly that no structure is visible, but in the majority of cells the cytoplasm has a fine, interlacing linear structure or there are ill-defined amorphous bluish flecks. Plasma cells are often spoken of as having a granular cytoplasm, but well-defined granules such as are observed in neutrophilic and eosinophilic myeloid cells are not seen. In some cells the cytoplasm appears foamy or there may be multiple vacuoles of various sizes. A collarlike layer of clear hyaline material may be seen sometimes at the periphery of the cell, or the outer portion of the cell may be light and relatively structureless with

Fig. 3.—Drawings showing plasma cell variants in bone marrow films, plasma cell myeloma. A, B, and C, Early plasma cells with cytoplasmic streamers; D, plasma cell with delicate nuclear chromatin and irregular streamers extending into hyaline periphery; E, mature plasma cell with suggestive chromatin of histiocyte; F, plasma cell with cytoplasmic extensions.

hairlike bluish strands extending into this area from the darker stained central portion of the cell (Fig. 3D). Homogenous spherical bodies, usually acidophilic but staining various shades of red to blue (Russell bodies), are occasionally demonstrable (Fig. 4C). The mature plasma cell and its progenitors react negatively with peroxidase stains.

Fig. 4.—Photomicrographs of plasma cells in bone marrow, plasma cell myeloma. A, Multinucleated giant cell with vacuoles in cytoplasm and ill-defined margin, cytoplasmic debris; B, plasma cell showing hairlike cytoplasmic streamers; C, plasma cell with eosinophilic globules (Russell bodies); D, plasma cells: one with two nuclei, giant form with vacuoles, intermediate nucleus, and cytoplasmic projections, and one in mitosis. Rouleaux formation.

The distribution of plasmoblasts, early plasma cells, mature plasma cells, and atypical forms in each of our patients was determined by analyzing 100 plasma cells. The results are graphically represented in Fig. 5. It is noted that

plasmoblasts are present in varying numbers in forty-three cases, that the early forms are found in all films, and that atypical cells are present in significant numbers in the majority of cases. Cells showing degenerative changes were included with the atypical cells.

Fig. 5.—The distribution of plasmoblasts, early plasma cells, mature plasma cells, and atypical forms in fifty-five patients with plasma cell myeloma.

In plasma cell myeloma there is evidence of increased and abnormal cell division. Mitotic figures are usually demonstrable and cells with multiple nuclei common (Fig. 4A, D). The number of nuclei in a given cell varies from two to six. The nuclei are characteristically separated from each other, are round or oval, and are of the same size; however, indented or lobulated nuclei, nuclei of different sizes, and nuclear fragments are sometimes seen.

Plasma cells tend to appear in pairs or in small groups in normal marrow. In plasma cell myeloma there may be large nests of contiguous cells which are often flattened or polyhedral in shape.

One of the characteristics of the plasma cell as seen in normal bone marrow and as an exaggerated and prominent feature in plasma cell myeloma is the marked variation in shape of the cells and the tendency for the cells to be frayed and ragged in outline. These cytoplasmic projections may be short and blunt or long, slender, and hairlike (Figs. 3 and 4). Irregularities and fragmentation of the cytoplasm have been noted by various authors,^{1, 2, 11, 12} but little emphasis has been placed upon this feature in descriptions of cells or in illustrations. The cells that have ill-defined margins and tapering tortuous filamentous streamers constitute from 10 to 50 per cent of the plasma cells. The streamers are characteristic of the cells at all stages of maturation but are most numerous in the earlier cells. It is apparent from the study of bone marrow films from patients with plasma cell myeloma and from nonmyelomatous conditions that plasma cells are fragile, that their margins are readily torn and smudged, and that partial disintegration is characterized by hyaline and filamentous cytoplasmic protrusions which merge in a nebulous manner with the background. In many preparations it is possible to show continuity between the cells and the cytoplasmic debris (Fig. 4A). It is probable that the increased and abnormal serum proteins found in association with plasma cell myeloma have their origin in plasma cells and that the extracellular structures seen in the marrow films are visible manifestations of these proteins at the site of their formation.

Plasma cells with cytoplasmic streamers are less striking in tissue sections or in marrow films made by techniques which require mechanical manipulation and delay than in films made directly. When 1 to 5 c.c. of marrow are withdrawn, an anticoagulant is added, the material centrifuged, and the supernatant cellular layer mixed before spreads are made, the more fragile cells are destroyed, and the remaining cells tend to assume a spherical form.

The plasma cells in plasma cell myeloma vary greatly in size as well as in shape. The predominant cells are larger than normal, and giant forms are often found (Fig. 4A and D).

Acidophilic globules or Russell bodies (Fig. 4C) were present in the cytoplasm of the plasma cells of several of our patients and have been observed by one of us (L. W. D.) as a prominent feature in a single case of a patient with plasma cell leucemia not included in this series, but these structures were not demonstrable in the majority of cases. No cells were observed which contained in their cytoplasm red cells, pigment, or other identifiable particulate matter.

The clear zone which is characteristic of normal plasma cells is not adjacent to the nucleus in individual cells in plasma cell myeloma.

There was a tendency toward a left shift in the myeloid, erythroid, and megakaryocytic elements, but there were no gross alterations in the maturation pattern of these cells. Lymphocytes constituted above 15 per cent in fourteen of the fifty-five cases, and the average lymphocyte percentage was 12. Eosinophiles were demonstrable in most films, but in no cases were they more than 4 per cent. Histiocytes were infrequent.

Rouleaux formation, cellular debris, and bluish background were striking in the majority of cases.

THE PERIPHERAL BLOOD

The plasma cells in the peripheral blood of fifty-three patients were estimated by noting the number per 1,000 leucocytes. No plasma cells were found in twenty-six cases, and 0.1 to 0.9 per cent were observed in nineteen cases. The number was 1 to 3 per cent in four cases and 4, 7, 21, and 46 per cent in individual cases.

The types of plasma cells found in the peripheral blood were analyzed according to eccentricity of nucleus, perinuclear clear zone, maturity of nucleus, presence of nucleoli, vacuoles in cytoplasm, and cytoplasmic streamers. The conclusions drawn were that cells comparable to those found in the bone marrow could be found in the peripheral blood, but that the peripheral blood cells as a class were more mature and tended to have less irregularity in shape and fewer cytoplasmic tags. Occasionally cells with distinct nucleoli were observed. Many cells were found which were difficult to distinguish morphologically from immature and atypical lymphocytes.

The differential count in the peripheral blood was not remarkable. There was a tendency toward a slight left shift in myeloid elements with occasional myelocytes and metamyelocytes in a few of the cases. There were occasional nucleated red cells. The platelets were normal in most of the cases but tended to be decreased in the terminal stages or in association with leucemic states.

Morissette and Watkins¹³ considered that the blood film was of aid in the diagnosis of plasma cell myeloma and stressed the importance of greasiness of the film, anemia, excessive rouleaux formation, immature erythrocytes and leucocytes, lymphocytosis, eosinophilia, and the presence of "myeloma" and atypical plasma cells.

The suspicion of plasma cell myeloma has occasionally been aroused in our laboratory by the finding of exaggerated rouleaux formation and by an increase in plasma cells, including early and atypical forms. Rouleaux formation, on the other hand, is a common and nonspecific finding. Atypical and early cell types and plasma cells in small numbers are often observed in nonmyelomatous conditions.

DISCUSSION

Individual atypical plasma cells closely resemble and may be impossible to distinguish from individual erythroblasts, early myeloid cells, and lymphocytes, but the cell maturation sequences of the various cell types are different, and there is little difficulty in distinguishing the plasma cells as a group from myeloid, erythroid, and lymphoid groups. Cells of the myeloid series have definite and well-defined granules, whereas plasma cells have a mottled appearance or linear cytoplasmic structure. Myeloid cells as a class have a smooth margin and seldom have a prominent unstained area near the nucleus, whereas plasma cells have irregular shapes and a clear zone adjacent to the nucleus. The peroxidase stain may be helpful in making the distinction between cells of the myeloid and plasma cell types. Erythroblasts and atypical lymphocytes

may have cytoplasm which stains darkly, but these cells as a rule have a relatively large nucleus, the clear zone is not prominent, there are not likely to be vacuoles or spongy cytoplasm, and there are seldom cytoplasmic streamers extending from the periphery of the cell.

All of the patients with myeloma in our series were of the plasma cell type. Early myeloid cells were found in many films; however, this was not accepted as evidence for the myeloid type of myeloma, for there were no demonstrable transitions between the myeloid cells and plasma cells. Myeloid cells are normal bone marrow constituents, and these cells are to be expected in varying numbers in any malignancy involving the marrow. In our opinion, to call a plasma cell myeloma a myeloid myeloma because there are myeloid cells also present is as illogical as it would be to call a myeloid leucemia a plasma cell leucemia because there are plasma cells demonstrable.

In the literature there are frequent references to the "myeloma cell" as if there were one cell type distinctive of the disease. The descriptions of the so-called "myeloma cell" vary in minor details but in general are those described previously as plasmoblasts, the essential features being an early cell with a round eccentric nucleus containing a large and well-defined nucleolus.^{14, 15} The demonstration of plasmoblasts and the presence of large numbers of these very early cells is of great value in the diagnosis of malignancy of the plasma cell type, but there is little justification for picking out this one cell in a sequence and giving to it a nondescriptive and nonspecific name.

It was possible to find in the bone marrow preparations from patients with plasma cell myeloma transitions between the plasmoblasts and undifferentiated fixed tissue cells of the reticulum type. Our observations lend support to the thesis held by many workers that the plasma cells arise from primitive reticulum cells and exist as a specific and distinctive strain of cells.

It is apparent that there is no sharp line of demarcation between the solitary plasmocytoma, plasma cell myeloma, and plasma cell leucemia, for the types of cells found in these three conditions are similar, there are all degrees of variation, and the same patient may exhibit all three features of the disease in different stages of the process.

The bone marrow examination is useful not only in confirming or making the diagnosis of plasma cell myeloma but in differentiating this disease from other diseases. The finding of a normal or only slightly increased number of plasma cells which are of a mature type is of great value in ruling out plasma cell myeloma. In doubtful cases the repetition of the marrow examination at a later date or puncture at a different level of the sternum is indicated.

SUMMARY

Films made from the sternal marrow of fifty-five patients with plasma cell myeloma revealed:

1. Increased cellularity.
2. Relative and absolute increase in plasma cells, 4 to 90 per cent, with more than 10 per cent in forty-eight cases.

3. Increased number of plasmoblasts and early plasma cells and plasma cells in mitosis.
4. Grouped plasma cells.
5. Nuclear abnormalities in plasma cells:
 - (a) Multiple nuclei
 - (b) Nuclear fragments
 - (c) Indented and lobulated nuclei
6. Cytoplasmic abnormalities in plasma cells:
 - (a) Displacement or absence of relatively unstained areas in some of the cells
 - (b) Variations in size with tendency toward large forms
 - (c) Marked irregularities in shape with blunt and hairlike cytoplasmic projections and tortuous and ragged cytoplasmic streamers; cytoplasmic debris
7. Relative and absolute decrease in myeloid, erythroid, and megakaryocytic elements with a tendency toward immaturity. Slight lymphocytosis. Eosinophiles usually demonstrable.
8. Rouleaux formation.

Plasma cells with eosinophilic globules (Russell bodies) were demonstrable in several cases but were not observed in the majority.

No plasma cells were found in the peripheral blood films while 1,000 leucocytes were counted in twenty-six of fifty-three cases; less than 1 per cent were found in nineteen, 1 to 3 per cent in four, and more than 4 per cent in four. Plasma cells in the peripheral blood were similar to those found in the bone marrow but tended to be more mature and less irregular in shape.

No instances of myeloid, erythroid, or lymphocytic types of multiple myeloma were observed.

The cells described in the literature as "myeloma cells" have morphologic characteristics of early plasma cells. The term "myeloma cell" should be discontinued, for it is nonspecific and nondescriptive.

This study lends support to the following theses which have been proposed by others:

1. Plasma cells arise from reticulum cells.
2. Plasma cells constitute a distinct strain of cells morphologically different from myeloid, lymphoid, and erythroid types.
3. There is no sharp line of demarcation between solitary plasmocytoma, plasma cell myeloma (multiple plasmocytoma), and plasma cell leukemia.

THE INFLUENCE OF HEAT AND FORMALIN UPON THE RH AGGLUTINOGEN

HERBERT H. LUBINSKI, M.D., AND JOSEPH C. PORTNUFF, M.D.
MONTREAL, QUEBEC

DURING the course of a series of experiments on the Rh factor, differences between the Rh agglutininogen and the A and B agglutinogens were noted in regard to their sensitivity against heat. It was observed that red cells suspended in saline and heated to 56° C. lost their agglutinability by anti-Rh serum, whereas the agglutinability of these red cells by anti-A and anti-B sera was apparently not affected. To corroborate these chance observations the following experiments were performed.

Freshly drawn Rh-positive cells of good agglutinability were washed three times and then resuspended in normal saline to a 2½ per cent concentration. From this stock suspension 2 c.c. each were then transferred into a series of small tubes equal in regard to size, lumen, and thickness of wall. The tubes were stoppered with corks and placed in a water bath at 56° C. for periods ranging from five to twenty minutes; after heating, the tubes were cooled immediately. The red cells were then tested in the usual way for their agglutinability by adding 2 drops of the cell suspension to 2 drops of undiluted serum. After shaking, the mixtures were placed in the incubator for one-half hour and centrifugalized for one minute at a speed of 1,200 r.p.m. The results were read with the help of a magnifying glass.

It is shown in Table I that, increasing with the period of heating, the agglutination by anti-Rh serum is diminished or rendered negative, whereas the agglutination by anti-A and anti-B sera remains unchanged, that is, 4 plus.

Different strains of red cells behaved differently, in so far as some were more affected by the heating process others less.

Since each experiment was finished on the same day that the blood was drawn, the differences between the various strains cannot be attributed to an aging process of the red cells.

In a second series of experiments the reactivity of heated red cells was tested against anti-Rh agglutinating serum, anti-Rh blocking serum and anti-A, anti-B, anti-M, and anti-N sera. The technical procedure was the same as has been described, with the exception that the washed red cells were resuspended in saline as well as in 30 per cent albumin made from bovine plasma. This was necessary for the test with blocking sera.

Given in Table II is an example of such an experiment. It shows that after five minutes heating the red cells become inagglutinable by anti-Rh agglutinating as well as anti-Rh blocking serum, whereas the agglutination by anti-B and anti-N sera remains unaffected after twenty minutes, is slightly diminished after one hour, and is still present, though weakened, after two hours of heating.

Heating periods of one hour and longer were possible only with red cells suspended in albumin. Red cells suspended in saline were almost completely hemolyzed after twenty minutes' heating, at which time the cells in albumin did not show any signs of hemolysis. The fact that the red cells lost their reactivity with agglutinating as well as with blocking serum supports Wiener's conception that all Rh antibodies (univalent and bivalent) act upon the same cell receptor.

In a third series of experiments the influence of chemicals upon the Rh factor compared to the A and B factors was studied. Out of several substances which had been tested, the only one which produced a selective effect was formalin.

Red cells washed three times were resuspended in normal saline containing different amounts of formalin, the final concentration of the latter ranging from 0.15 to 1.0 per cent. The formalinized red cell suspensions were kept in the refrigerator overnight; the next morning the agglutinability was tested.

Two examples of the findings are given in Table III. From these it can be seen that formalin in low concentrations inhibits the agglutination by anti-Rh serum. The agglutination by anti-A and anti-B sera is not or is to a lesser

degree affected. Concentrations higher than 1 per cent have an inhibiting effect upon the agglutination by anti-A and anti-B sera as well.

Since increasing the length of heating time has a hemolyzing effect upon red cells suspended in saline, a control experiment was set up in which hemolysis was produced by lowering the NaCl concentration of the suspending solution (fragility test). Red cells were suspended in 0.4 per cent saline which, it was found, produced a distinct but not complete hemolysis. However, the partly hemolyzed red cells gave the same 4 plus reaction with anti-A, anti-B, and anti-Rh sera as the control. Therefore, the loss of agglutinability by anti-Rh serum is not caused by the process of hemolysis accompanying the heating.

It is known that heated red cells are less agglutinable by weak anti-A and anti-B sera. However, the titers of the used anti-A, anti-B, and anti-Rh sera were the same— $\frac{1}{128}$; the titer of the Rh blocking serum was $\frac{1}{32}$, and the titer of the anti-N serum was $\frac{1}{2}$. Therefore, the differences in the agglutinability between heated and nonheated cells cannot be explained by weakness of the anti-Rh serum.

One may only speculate about the cause of the described observation. Since a similar difference is known to exist between the H and the O agglutinins of some bacilli and since this difference is connected with the location of the agglutinogens, it may be that the A and B and the M and N agglutinogens are situated within the cells, whereas the Rh agglutininogen may be located on the surface.¹ It may be that the Rh agglutinogens are less numerous than the others, as suggested by Wiener,² and therefore are destroyed faster. A third possibility is a difference in the chemical structure of the different agglutinogens.

SUMMARY

Heating of red cells to 56° C. for five to twenty minutes diminishes or destroys their agglutinability by anti-Rh agglutinating and blocking sera, whereas the agglutinability by anti-A, anti-B, anti-M, and anti-N sera is apparently not affected.

Addition of formalin (0.1 to 1.0 per cent) to red cell suspensions reduces the agglutinability by anti-Rh serum much more than the agglutinability by anti-A or anti-B sera.

While this paper was being prepared for publication, Calvin and associates³ reported upon a similar investigation in which the same conclusions were arrived at regarding the heat sensitivity of the Rh antigen. They suggest a protein denaturation as a basis for the destruction of the antigen.

BENZIDINE-NEGATIVE STOOLS DURING IRON THERAPY

STEVEN O. SCHWARTZ, M.D., CHICAGO, ILL., AND LIEUTENANT CHARLES S. VIL,
MEDICAL CORPS, ARMY OF THE UNITED STATES*

THE possibility that the administration of iron salts to patients with suspected gastrointestinal bleeding will interfere with the benzidine reaction of the stools is of considerable practical importance. Our interest in this problem was enhanced by the clinical significance of the question, since it is the patient with possible gastrointestinal bleeding who most often is in need of iron therapy. The present study was undertaken in an attempt to clarify this point.

Neither the literature nor laboratory texts offer a definitive answer. Ogilvie¹ believe that iron compounds do not interfere with the benzidine test and suggested that the exclusion of meat, excepting in large quantities, was unnecessary. Johnson and Oliver² found false-positive benzidine reactions following the administration of considerable amounts of meat, but the benzidine test was negative on iron administration. In their series seven of the patients received 12 gr. of ferrous sulfate and nine received 30 grains. Bell,³ on the other hand, found the benzidine test more sensitive than the guaiac test and recommended that iron compounds, as well as iodides, be eliminated from the diet during search for occult blood. Burger² concluded, from the two cases studied, that iron and ammonium citrate do not interfere with the guaiac test but that the benzidine test is consistently positive due to the administered iron.

MATERIAL AND METHODS

Nineteen young women patients, known to be free from gastrointestinal disease, were used in the experiments. In these patients twenty-eight series of observations were made as follows: four during ferrous sulfate administration; seven during ferrous sulfate and copper sulfate administration; six receiving Iberin; one getting Otoferrin; two while on high-iron, meat-free diets; and eight eating high-meat diets.† In most cases meat-free diets were started and two or three successive negative stools were awaited before iron therapy was begun. All patients were kept on the test substance for at least five days, during which time they remained on meat-free diets. Stools were tested before, during, and after the therapy period.

In examining for blood a portion of feces from the center of the specimen was spread out on a piece of white absorbent paper; to this a few drops of freshly prepared benzidine

Received for publication, Nov. 29, 1946.

*Formerly Resident in Medicine at the Cook County Hospital.

†The iron preparations were administered in the following dosage: Ferrous sulfate tablets 0.3 Gm., t.i.d.; Cofron tablets, 2, t.i.d. (solution ferrie pyrophosphate, 3.35 gr. copper sulfate, 0.0606 gr. per tablet); Iberin capsules, 3, t.i.d. (iron and ammonium citrate, 5 gr. thiamine hydrochloride, 0.375 mg.; riboflavin, 0.125 mg.; nicotinamide, 5 mg.; liver concentrate, 4 gr. per capsule); Otoferrin, 4 drams, t.i.d. (3.9 gr. of "ovoferrin, a form of colloidal iron" [65 mg. iron] per dose).

The diets were approximately the following: The general ward diet contained about 75 to 80 Gm. of protein and 13 or 14 mg. of iron. The high-iron, meat-free diet contained about 90 to 100 Gm. of protein and 20 to 25 mg. of iron. Special attention was given to large servings of whole wheat and oatmeal cereals, eggs, vegetables, (as green peas), fruits (as apricots, peaches, prunes), and bread. The meat-free diet contained about 70 Gm. of protein and 10 to 15 mg. of iron. It was similar to the general ward diet, but milk and eggs were substituted for meat. The high-meat diet contained only 80 Gm. of protein and 14 mg. of iron, but this was derived mostly from meat sources.

TABLE I. SUMMARY OF RESULTS OF STOOL STUDIES ON VARIOUS DIETARY AND THERAPEUTIC REGIMENS

solution were applied. The benzidine solution was prepared by adding 5 c.c. of glacial acetic acid to 2 gr. (approximately equivalent to the amount of powdered benzidine on a knife tip) of powdered benzidine in a clean, dry test tube. When this was partially or completely dissolved, 2½ c.c. of hydrogen peroxide were added. The same reagents were used throughout the determinations, and the benzidine solutions were frequently tested with blood diluted in water and stools known to contain occult blood. The benzidine test was interpreted as follows: plus, thirty seconds or more for the development of a bluish-green reaction; 2 plus, fifteen to thirty seconds for the development of a bluish-green color reaction; 3 plus, five to fifteen seconds; 4 plus, immediate development of the color (less than five seconds).

DISCUSSION

Stools from only eight patients were obtained on the first day of a meat-free diet. Of these stools four were positive for blood. One patient had benzidine-positive stools the second and third days as well. The others had benzidine-negative stools after the first day. Five out of eight patients who were placed on high-meat diets developed benzidine-positive stools. In these patients the benzidine test became positive twenty-four to forty-eight hours after the meat was added to the diet and remained intermittently positive during the period of observation.

The eighteen patients who received some form of iron therapy received it over a period of 118 days. During this time eighty-one stool examinations were performed. In this series only one stool (Patient 10) was found to be benzidine positive during iron administration (Table I).

SUMMARY AND CONCLUSIONS

1. Eighteen patients on meat-free diets were given various iron preparations in therapeutic doses. The stools, with a single exception, remained negative to the benzidine test.

2. Stools became negative to the benzidine test in a maximum of three days on meat-free diets.

3. The majority of patients tested had benzidine-negative stools even on normal diets.

4. High food-iron, but meat-free diets did not produce stools with positive benzidine reactions.

5. High-meat diets frequently gave positive stool benzidine reactions within twenty-four to forty-eight hours of their initiation.

HYPERPARATHYROIDISM AND PARTIAL HEART BLOCK

SHOLOM O. WAIFE, M.D.

BALTIMORE, Md.

THE effect of alteration in the level of serum calcium on the heart, as evidenced in the electrocardiogram, has been known for some time. Hypocalcemia leads to a prolonged electrical systole, a prolonged Q-T interval,^{1, 2} while hypercalcemia leads to a short Q-T interval.^{1, 3}

The effect of serum calcium changes on the P-R interval is less clear. Gold and Edwards⁴ injected parathyroid hormone into dogs and found varying degrees of heart block. Others⁵ injected calcium chloride into dogs, or man, and found among other things recurring A-V block. Atropine was found to prevent the prolongation of the P-R interval when calcium was given to rabbits,⁶ showing that calcium stimulates vagal activity. Furthermore, in guinea pig heart perfusion experiments, Spealman⁷ found that the P-R interval lengthened as the calcium ion concentration in the perfusate increased. The Q-T interval was altered (lengthened) only when the calcium concentration decreased.

On the other hand, Segall and White⁸ and Berliner⁹ reported no prolongation of the P-R interval when calcium was injected into man. However, one patient with hyperparathyroidism (blood calcium of 19.2 mg. per cent) had a P-R interval of 0.23 second which returned to normal after removal of an adenoma.³

This case is reported because of the marked degree of heart block which persisted for some time after a parathyroid adenoma was removed and after the serum calcium fell to subnormal levels. The duration of electrical systole, on the other hand, varied with the serum calcium.

CASE REPORT

R. C., a 17-year-old boy, who had completely recovered from acute nephritis at the age of 12, developed fatigability, low back pain, and three months later aching in the thighs. Later, polyuria, nocturia, and pain on mastication were noted, and ten months after the onset a fracture of the right humerus occurred. This led to x-ray studies, with the discovery of typical osteitis fibrosa cystica and diffuse demineralization of all bones.

The only noteworthy physical findings were the high pulse pressure, with a blood pressure of 154/50 mm. Hg, and the vigorous heart action, with no sign of an aortic valve lesion or cardiac enlargement. Most observers failed to feel a nodule in the area of the lower pole of the right lobe of the thyroid, but this was noted by Dr. E. Goetsch who removed a parathyroid tumor measuring 2.5 by 5 by 2.5 cm. and weighing 14.5 grams.

Laboratory examination of the blood and urine was negative except that the patient had marked calcinuria, 1.2 Gm. per twenty-four hours, after three days on a low calcium diet. The normal output on that regime is less than 0.2 gram. The preoperative serum calcium was 17, phosphorus 1.8, and alkaline phosphatase 32.2 mg. per cent. The electrocardiogram on admission to the hospital revealed a P-R interval of 0.38 second.

The levels of blood calcium, phosphorus, and alkaline phosphatase and the duration of the R-R, P-R, and Q-T intervals are shown in Table I.

Q-T interval†			.29			.34			.36			.408			.387		.36

*Values as milligrams per cent.

†Time in seconds, average of five consecutive readings in lead where waves were best defined, usually Lead II.

Thus it can be seen that as the serum calcium returned to normal on the third postoperative day the P-R interval shortened from 0.38 to 0.24 second. Six days after operation the P-R interval was 0.20 second, while the serum calcium was falling from 8.5 to 7.5 mg. per cent. However, with a subsequent fall in calcium concentration, the P-R interval was maintained at about 0.24 second, until three weeks after operation when it was 0.21 second. At that time the serum calcium concentration was 8.0 mg. per cent.

It is true that at slower cardiac rates the P-R interval may be somewhat lengthened, but the P-R interval changes in this case are much greater in magnitude than those related to heart rate. Furthermore, regardless of rate, the P-R interval should not exceed 0.20 second at rates under 70 per minute.

It seems obvious that the prolonged hypercalcemia had produced changes in the A-V system which reverted slowly to normal in the weeks after operation. The Q-T interval varied as expected, short in relation to heart rate (R-R) with hypercalcemia and prolonged with hypocalcemia.

Parenteral atropine in doses of 0.6 to 1.2 mg. had no effect on the prolonged P-R interval.

DISCUSSION

It is generally admitted that the formulas relating normal Q-T intervals and heart rate are not satisfactory, witness the numerous new formulas¹⁰ (Table II). If Hegglin and Holtzmann's formula¹¹ is used, the patient had a Q-T interval within the normal range preoperatively in spite of marked hypercalcemia. This Q-T interval of 0.29 second would also be just within the range described by White and Mudd.¹² At any rate it is clear that the chief alteration was in the prolonged P-R interval, 0.38 second.

TABLE II. EXPECTED Q-T INTERVALS BASED ON HEART RATE ACCORDING TO VARIOUS FORMULAS

Q-T INTERVALS	DATE			
	3/14	3/18	3/21	3/24
Actual	.29	.34	.36	.41
Expected:				
Schlamowitz ¹⁰	.309	.319	.317	.351
Hegglin and Holtzmann ¹¹	.324 ± .04	.335 ± .04	.333 ± .04	.369 ± .04
Ashman ¹⁴	.33	.34	.34	.369
Bazett ¹⁵	.308	.32	.32	.35
Frederica ¹⁶	.337	.345	.34	.367

The experimental evidence for A-V block due to hypercalcemia is found in the isolated fiber technique,¹³ in which it was shown that increases in calcium concentration eventually produced neuromuscular block. Excess of ionized calcium gradually blocked nerve-muscle transmission by lowering the electrical excitability of the muscle fiber adjacent to the end plate. However, this would not explain the persistence of the prolonged P-R interval while the serum calcium fell to levels producing latent tetany.

The prolonged P-R interval was probably not due to a vagal effect, as atropine in doses sufficient to cause mydriasis and dryness of the mouth did not alter it. This, then, differs from the form of heart block associated with calcium reported by Hoff and associates.⁶ The cause of this heart block is unknown.

SUMMARY

A case of hyperparathyroidism is presented. It shows marked prolongation of the P-R interval and the expected increase in duration of systole with fall in serum calcium.

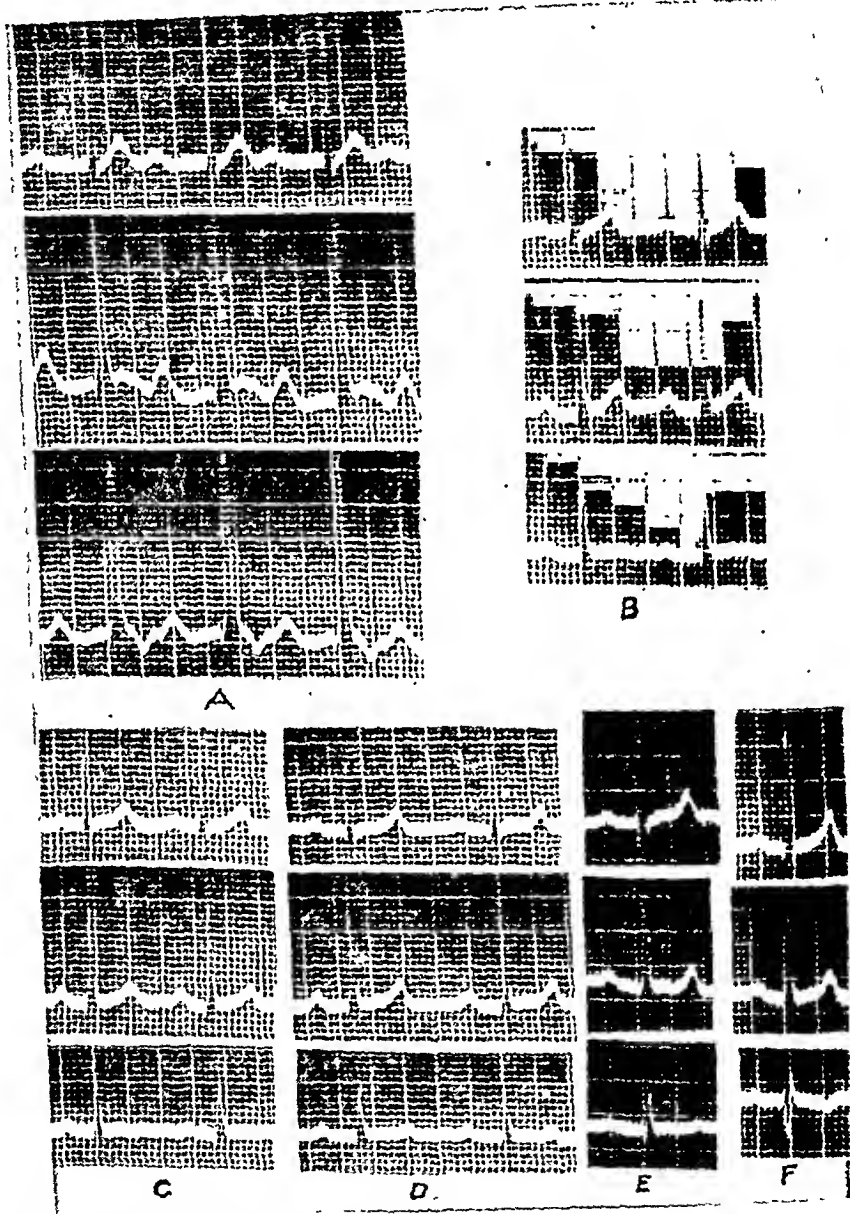

Fig. 1.—Electrocardiograms. Limb leads. (A) Preoperatively. In this film the standardization was inadvertently doubled so that 1 mv. gives a deflection of 2 cm. (B) Postoperatively, $\frac{1}{2}$ sec. (C) Postoperatively, $\frac{1}{2}$ sec. (D) Postoperatively, $\frac{1}{2}$ sec. (E) Postoperatively, $\frac{1}{2}$ sec. (F) Postoperatively, $\frac{1}{2}$ sec.

These two phenomena are independent of each other, as evidenced in Fig. 1D and Fig. 1E, in which a prolonged P-R interval (0.24 second) was found together with abnormally long Q-T intervals, when the serum calcium was below 8 mg. per cent.

Incomplete heart block may be found in the presence of hypercalcemia. It may not completely disappear when the serum calcium level returns to normal or subnormal levels. Atropine did not alter the P-R interval in this case. The effect of changes in blood calcium on the P-R interval is still obscure and needs further study.

SENSITIVITY OF *EBERTHELLA TYPHOSA* TO PENICILLIN FRACTIONS G AND X

HENRY WELCH AND W. A. RANDALL
WASHINGTON, D. C.

VARIOUS investigators have shown the increased effectiveness of penicillin X over other types of penicillin in inhibiting the growth of various organisms in vitro and in exhibiting an increased protective action in vivo.^{1,3} This increased activity of penicillin X is not only directed against organisms which are highly sensitive to penicillin but also applies to gram-negative bacilli such as *Klebsiella pneumoniae*¹ and *Escherichia coli*² which are relatively resistant. The strain of *Esch. coli* used by Libby and Holmberg² was inhibited by 133.9 units of penicillin G and by 46.875 units of penicillin X. Recently, Bigger⁴ has shown that *Eberthella typhosa* is inhibited in the test tube by penicillin and that this action of penicillin is potentiated by sulfathiazole. Evans⁵ reported that most of the sixty-four strains of *E. typhosa* tested were inhibited by 5 to 10 units of penicillin. Clinical confirmation of Bigger's work was obtained by McSweeney⁶ who treated several cases of typhoid fever with a combination of penicillin and sulfathiazole. Relatively large doses of penicillin were used, 10,000,000 units being given over a period of four days, in combination with 34 Gm. of sulfathiazole. In some cases this regimen was repeated, and encouraging results were obtained. While this dose of penicillin appears to be large when expressed in units, actually it is rather small when expressed in grams. Ten million units of penicillin are equal to only 6 Gm., and this was given over a four-day period (1.5 Gm. per day). Actually over five times as much sulfathiazole as penicillin was administered. Owing to the low toxicity of penicillin it can be given in quantities which will result in blood levels of 40 to 80 units per cubic centimeter of serum. It is, therefore, logical to treat diseases in which the infecting organism is susceptible to amounts of penicillin which can be maintained in the blood stream by giving large doses of the drug. Indeed, in view of the results obtained in syphilis by Lloyd-Jones and Allen⁷ with a single daily injection of penicillin, there is some question as to the necessity of maintaining high levels over long periods of time. In view of the interest in the treatment of typhoid fever with penicillin, it seemed pertinent to report some results obtained several years ago on the action of penicillins G and X on *E. typhosa*.

Two methods were used for determining sensitivity. The first was a serial dilution method in which dilutions of both of the penicillin fractions and culture under test were made in broth. The inoculum consisted of a 1 per cent dilution of an overnight broth culture of the organism in the test medium. The tests

From the Division of Penicillin Control and Immunology, Food and Drug Administration.
Received for publication, Nov. 25, 1946.

were incubated in a water bath at 37° C. and results read at six hours and again at twenty-four hours. The end point was the smallest amount of penicillin resulting in complete inhibition of growth. Twenty-nine strains of *E. typhosa* were studied using the serial dilution technique. The second method was a cylinder plate assay similar to that described for *Staphylococcus aureus*,⁸ except that instead of the latter organism the various strains of *E. typhosa* were used as the test organism. Since five strains produced unsatisfactory growth in the seed layer, only twenty-four cultures were tested by this technique. The plate method employs two dosage levels of penicillin, 5 and 20 units (ratio 1 to 4). The penicillin G (370 units per milligram) was considered to be the standard and the penicillin X (900 units per milligram) was treated as the unknown. The potency of penicillin X was computed according to the method of Knudsen and Randall.⁸

The penicillin G was the F.D.A.* working standard which had a potency of 370 units per milligram when compared to the master standard, crystalline sodium penicillin, which has a potency of 1,667 units per milligram. On the same basis crystalline penicillin X has a potency of 900 units per milligram. These potencies are all based on the *Staph. aureus* plate assay. The F.D.A. working standard had been shown to consist largely of the G fraction.

In Table I are shown the results obtained with twenty-nine typhoid strains in the serial dilution test. At six hours only three strains were inhibited by 0.75 units of penicillin G, while twenty-eight strains failed to grow in the same amount of penicillin X. In twenty-four hours the difference is less striking since twenty-six strains are inhibited by 3 units or less of penicillin X, while twelve strains failed to grow in the presence of the same amount of penicillin G. Of the twenty-nine strains tested by the dilution method, twenty-four were twice as sensitive to penicillin X as to penicillin G on a unit per milligram basis, one strain was three times as sensitive, and four strains were four times as sensitive.

TABLE I. EFFECT OF PENICILLINS X AND G ON *E. TYPHOSA*

				6 HR.		24 HR.			
<i>Type G Serial Dilution Method</i>

Potencies of "X" expressed as per cent of standard (G)	200 to 300	300 to 400	400 to 500	500 to 600	600 to 700	700 to 800

*F.D.A., Food and Drug Administration.

In Table II the results of the cylinder plate tests are given. This method of testing reveals an even greater difference between the two penicillin species than was shown by the serial dilution test. All strains were at least twice as sensitive to penicillin X as to penicillin G, and three strains were seven or eight times as susceptible. If the potency of penicillin X is computed in units per milligram, the activity varies from 1,800 units per milligram to 7,200 units per milligram, depending on the strain of *E. typhosa* used for assay.

DISCUSSION

The known properties of penicillin and streptomycin indicate that the latter drug should be the one of choice for the treatment of gram-negative infections. Yet recent experience with streptomycin in the treatment of typhoid fever⁹ indicates that this antibiotic is of questionable value in spite of apparent in vitro sensitivity of the typhoid organism to it. Conversely, although it is generally accepted that the typhoid organism is resistant to penicillin, McSweeney⁶ has successfully treated cases with this drug augmented by sulfathiazole. As a matter of fact, based on the data presented in these studies and those of Evans,⁵ there is reason to believe that penicillin alone should be an effective treatment in this disease when given in the proper doses. On the basis of these studies all twenty-nine strains of *E. typhosa* were inhibited in a yeast-beef broth at pH 7.0 by approximately 12 units per cubic centimeter or less of penicillin (7.2 gamma). When two of these strains were tested in the same broth for their sensitivity to streptomycin, 25 gamma were required to effect complete inhibition. Thus, on a weight basis, over three times as much streptomycin as penicillin was required for inhibition of these strains. When a comparison of the resistance of *E. typhosa* to the two antibiotics is made on a weight basis, the apparent advantage of streptomycin because of its characteristic attack on the gram-negative organisms is considerably minimized. Furthermore, the characteristic rapid and marked increase in resistance of gram-negative organisms to streptomycin both in vivo¹⁰ and in vitro¹¹ argues against the therapeutic use of this drug, particularly where another less toxic drug (penicillin) is available without these disadvantages.

The dose of penicillin which would apparently be effective in the treatment of typhoid fever is not a large one in terms of weight of drug utilized. In Keefer's⁹ recent publication on the use of streptomycin in typhoid fever, doses of 3 to 5 Gm. per day are recommended. Doses of penicillin such as these should result in blood levels more than adequate to be effective against the most resistant strains of *E. typhosa* reported in these studies or in those reported by Evans.⁵ The wide range between the therapeutic and toxic doses of penicillin as compared to the range between these doses of streptomycin is further argument in favor of penicillin therapy for typhoid fever.

Unfortunately, at the present time there is no commercial production of penicillin X. There is little advantage, if any, to the production of this penicillin fraction at the expense of the regular production of commercial penicillin (largely fraction G). So far, penicillin X has been shown to be quantitatively superior to penicillin G only; until a qualitative difference between penicillins X

and G can be demonstrated which would warrant the extra expense of producing penicillin X, it is unlikely that it will become commercially available. It is obvious, however, that in the case of typhoid fever considerably less than half as much penicillin X as penicillin G would be necessary in the treatment of this disease.

SUMMARY AND CONCLUSIONS

1. Of twenty-nine strains of *E. typhosa* tested all except one were inhibited by 12 units or less of penicillin G, in twenty-four hours.
2. All of the strains were inhibited by 6 units or less of penicillin X.
3. When the plate method was used to determine sensitivity, penicillin X was from two to eight times as effective as penicillin G.
4. A favorable response should be obtained in the treatment of typhoid fever provided sufficiently large doses of penicillin are utilized.

PHOSPHATASES AND INORGANIC PHOSPHORUS IN NORMAL HUMAN SERUM

JULES TUBA, PH.D., MAX M. CANTOR, M.D., AND HERMAN SIEMENS, M.D.
EDMONTON, CANADA

WITH THE TECHNICAL ASSISTANCE OF PERSIS A. CAPSEY, B.Sc.

INVESTIGATIONS of a clinical nature involving a consideration of the levels of human serum phosphatases and inorganic phosphorus necessitated the establishment of normal values in men and women. A group of 101 adults and 108 school children, aged 10 to 12 years, from the country around Edmonton volunteered to give blood in the fall of 1945, and their sera were assayed. According to Klasmer,¹ who worked with infants, the normal values for children have not been established with accuracy, and it was felt that the previously mentioned age group might be of interest. A seasonal variation in phosphatase activity was noted by Klasmer, and in order to find the effect of winter in the Edmonton area, estimations of inorganic phosphorus, acid, and alkaline phosphatases were repeated in the spring of 1946 with the sera of as many as possible of the fall donors.

EXPERIMENTAL

Serum phosphorus and serum phosphatases were determined by the micro-method of Shinowara and associates² as modified by Gould and Schwachman.³ Acid phosphatase was estimated at pH 5.3 and alkaline phosphatase at pH 9.3.

The unit of phosphatase activity is defined by Shinowara and associates as equivalent to 1 mg. of phosphorus as phosphate ion liberated during one hour of incubation at 37° C., with a substrate containing sodium β -glycerophosphate. hydrolysis not exceeding 10 per cent of the substrate, and optimum pH of the reaction mixture for "acid," 5.00 ± 0.15 , and for "alkaline," 9.30 ± 0.15 . Our estimations of phosphatase activity comply with this definition, except with regard to the optimum pH for acid phosphatase. The pH optimum is, however, a broad one, and we found no significant variation when estimations were made at pH 5.0 or 5.3.

RESULTS AND DISCUSSION

The mean values and the range of values for the different groups are summarized in Table I.

The acid phosphatase values which are very close to the range of 0.0 to 1.1 units reported by Shinowara show an increase during the winter in the adult groups. The Gutman and Gutman⁴ range is 0.5 to 2.0 units.

Important variations are found in alkaline phosphatase levels in relation to sex, age groups, and season. For both children and adults the values for male subjects are appreciably higher than for female subjects (30 and 20 per cent, respectively). The activity of the alkaline enzyme is approximately three

Women				
Fall	63	0.37 (0.0 to 1.2)	3.8 (2.0 to 7.0)	4.4 (3.2 to 5.4)
Spring	42	0.67 (0.0 to 1.2)	4.1 (2.5 to 7.3)	4.0 (1.8 to 5.4)
<i>Children, 10 to 12 Years</i>				
Boys				
Fall	51	—	12.8 (6.0 to 21.8)	5.9 (4.6 to 7.8)
Spring	44	0.61 (0.0 to 1.6)	13.5 (5.6 to 21.4)	4.9 (3.0 to 7.8)
Girls				
Fall	57	—	9.4 (6.0 to 17.8)	6.0 (4.8 to 7.8)
Spring	46	0.56 (0.0 to 1.6)	12.1 (5.6 to 17.1)	5.2 (2.0 to 6.4)

times greater among children than adults for both sexes. Bodansky⁵ reports a range of 1.5 to 4.0 units for adults and of 5 to 12 units for children.

The phosphorus values follow a similar though less marked trend. There is a very definite seasonal variation in the levels of phosphorus and alkaline phosphatase. In all groups there is a lower amount of serum phosphorus by spring, more especially in the case of children. At the same time, the winter has produced a definite rise in the amounts of alkaline phosphatase. Although active rickets was not observed in our donors the results noted corroborate Klasmer's suggestion that the seasonal variations noted may be associated with a winter diet and decreased exposure to ultraviolet rays.

SUMMARY

Serum phosphatases and inorganic phosphorus values were determined in the fall of 1945 on 101 adults and 108 children, aged 10 to 12 years. The estimations were repeated in the spring with fifty-six of the adults and ninety of the children. The average fall level of 11.1 Shinowara units for serum alkaline phosphatase for the children was almost three times that for the adults of 4.1 units. The activity of this enzyme was 20 to 30 per cent greater among the male than among the female subjects. An increase in the alkaline enzyme and a decrease in inorganic phosphorus, which were more marked in children than in adults, may be due to a winter diet and lack of sunshine. An increase in acid phosphatase was noted in the spring values of the adult groups.

LABORATORY METHODS

RAPID CONTINUOUS EXTRACTION AND DETERMINATION OF QUININE

GRANVIL C. KYKER AND MILDRED M. McEWEN*
CHAPEL HILL, N. C.

THE urgency of antimalarial work during the past few years has emphasized the importance of further studies on quinine as well as the search for new drugs. The ultimate progress of such studies is determined by the quantitative methods which are applicable to biologic material. Many improved methods have been reported recently by various workers.¹⁻⁹ Each of these methods requires the preliminary separation of the alkaloid from the biologic sample. In most of these this separation is accomplished by extraction with a suitable solvent. Ether,³ alcohol and ether,⁴ acetone and ether,⁹ chloroform,^{1,2} and ethylene dichloride⁷ are proposed either for stepwise manual extraction in a separatory funnel^{2, 4, 7, 9} or for a continuous process in specially designed apparatus.^{1, 3} One method, designed for blood plasma, employs a filtrate which retains the quinine after the proteins are precipitated with metaphosphoric acid.⁵ Once the alkaloid is separated from the sample, its measurement is based on either turbidimetric,^{3, 8} fluorometric,^{1, 4} colorimetric,^{2, 7, 9} or spectrophotometric^{6, 10} instrumentation.

Each of these methods offers advantages depending upon the material which is available and the requirements which are imposed by a particular investigation. Recently, certain investigators^{11, 12} have applied two or more methods simultaneously to the same materials. This has enhanced the value of the data and enabled additional interpretations, because no method which is specific for quinine⁸ has been designed and each when applied biologically may yield results which are vitiated by an indefinable amount of metabolic products.

In this report modifications of certain previous methods for quinine are described and adapted to a procedure which reduces the time and work of extraction and provides an extract of a biologic sample to which duplicate methods of assay may be applied simultaneously. These modifications became urgent during a study of the absorption of quinine in which the analysis of numerous fresh samples was required within brief periods. The existing methods which require manual manipulation of individual samples throughout the extraction become laborious for the analyst and limit his capacity. Also, the extended time which is required for continuous extraction by present methods^{1, 3} impedes concentrated periods of work. The time required for the continuous extraction of quinine from a sample of tissue has been reduced from four hours to fifteen minutes. This has been accomplished by changing

Received for publication, Nov. 14, 1946.

*Present address: Department of Chemistry, Queens College, Charlotte, N. C.

the design of the sample tube of an extractor previously recommended for continuous use with ether,³ so that it accommodates the continuous flow of a heavier-than-water solvent such as chloroform. The extractor permits a greater flow of solvent through the sample than its predecessor. Also, the solubility of quinine is higher in chloroform than in ether. Both of these factors contribute to the more rapid extraction.

APPARATUS

The extractor is similar in principle to others which have been reported¹³⁻¹⁵ for continuous liquid-liquid extraction with a solvent of greater density than water. Additional features are described which render the apparatus efficient and convenient for the biologic study of quinine and other alkaloids. It is simple to construct and is an interchangeable part of a unit for continuous operation with a solvent of less density³ which has had extended use in this laboratory. The adaptability of the complete unit to solvents of greater or less density than water expedites the analysis of identical samples by different methods as previously recommended. The details of construction and the interrelation of parts shown in Fig. 1 are self-explanatory. Additional versatility of the unit derives from its construction in different sizes, among which certain parts are interchangeable. The dimensions are presented in Table I and are indicated according to the labels in Fig. 1.

The absence of any horizontally connected parts or side arms contributes to a minimum of breakage and enables the compact alignment of multiple units in a battery. Batteries of six units each have proved convenient when mounted on horizontal rods 2 feet in length which are clamped at either end to vertical iron supports. When chloroform is used, smooth operation at the

Fig. 1.—Extractors for solvent of greater density: *A*, 50 c.c.; *a*, 10 c.c. Extractors for solvent of less density: *B*, 50 c.c.; *b*, 10 c.c. Punch marks for support of unit *A*: *p*. Complete apparatus, assembled with unit *A*: *C*.

beginning of the continuous process demands a readily adjustable source of heat. In this case the units in each battery are heated with a manifold of six ordinary gas burners which are equipped with adjustable chimneys for steady flames. On the other hand, when ether is used, a constant and moderate rate of heating is required. An electric heater which is easy to construct and has given years of heavy service is recommended.

The heating unit consists of a coil made by winding 140 turns of No. 22 Chromel wire about a $\frac{3}{8}$ inch mandrel and mounting in a suitable housing. The housing is an elongated right angle trough made by joining two pieces of $\frac{1}{4}$ inch Transite. Each wall of the trough is 2 by 24 inches on the inside. A support, 3 by 3 inches, is attached at either end. The pieces of Transite are joined securely with small 45 degree brackets and bolts. Small brass bolts through the end supports serve as binding posts for the electrical circuit. A cover, $2\frac{1}{4}$ by 24 inches, is undercut at 45 degrees along the sides and is provided with six holes, 1 inch in diameter, 4 inches apart, and 2 inches from either end. The unattached cover rests firmly and horizontally. Each extractor unit in a battery rests on its respective hole in the cover of the heater.

Rheostatic control is provided by a resistance whose specifications are identical to those of the heating element. This resistance is mounted with binding posts at one-tenth intervals on the back of a strip of Transite, 3 by 24 inches, which is clamped at each end to the vertical supports for the battery of extractors. Electrical connections are made with the binding posts from the front of the strip, on the back of which the resistance is mounted.

PROCEDURE

Digestion of Tissue.—Samples of tissue are digested by a procedure which is essentially that of Kelsey and Geiling.⁴ Slight modifications are introduced which improve the results after extraction of the alkaloid. The weight of the sample is roughly estimated in advance and defined as 1 part. To a beaker whose capacity is approximately 20 parts is added 5 parts of 2 per cent sodium hydroxide. The gross weight of the beaker, contents, and cover is recorded. Immediately after removal from its source, the sample of tissue is cut into 0.5 to 1.0 Gm. pieces and placed in the alkali. The weight of the sample is established by difference to an accuracy of 1 in 500. Additional alkali to make a total of 10 parts is added, in which the tissue is digested on a steam plate near the boiling point of the alkali. Hot water is added at intervals to compensate for evaporation, so that reduction in volume never exceeds one-half. The alkaline digest is transferred to a volumetric flask, the capacity of which is approximately 20 parts, and diluted to the mark. Aliquots of the resulting 5 per cent solution of tissue in 1 per cent alkali are extracted and analyzed according to the following procedure.

Extraction of Alkaline Digest.—An extractor of appropriate dimensions is selected and assembled as in Fig. 1C. Chloroform is added to the inner tube of the unit. The amount of solvent is 25 c.c. for either the 10 or 25 c.c. extractor and 50 c.c. for either the 50 or 100 c.c. extractor. An aliquot of the alkaline digest is introduced by pipette into the inner tube. Solvent which is displaced

Electrical connections are made with the binding posts from the front of the strip, on the back of which the resistance is mounted.

PROCEDURE

Digestion of Tissue.—Samples of tissue are digested by a procedure which is essentially that of Kelsey and Geiling.⁴ Slight modifications are introduced which improve the results after extraction of the alkaloid. The weight of the sample is roughly estimated in advance and defined as 1 part. To a beaker whose capacity is approximately 20 parts is added 5 parts of 2 per cent sodium hydroxide. The gross weight of the beaker, contents, and cover is recorded. Immediately after removal from its source, the sample of tissue is cut into 0.5 to 1.0 Gm. pieces and placed in the alkali. The weight of the sample is established by difference to an accuracy of 1 in 500. Additional alkali to make a total of 10 parts is added, in which the tissue is digested on a steam plate near the boiling point of the alkali. Hot water is added at intervals to compensate for evaporation, so that reduction in volume never exceeds one-half. The alkaline digest is transferred to a volumetric flask, the capacity of which is approximately 20 parts, and diluted to the mark. Aliquots of the resulting 5 per cent solution of tissue in 1 per cent alkali are extracted and analyzed according to the following procedure.

Extraction of Alkaline Digest.—An extractor of appropriate dimensions is selected and assembled as in Fig. 1C. Chloroform is added to the inner tube of the unit. The amount of solvent is 25 c.c. for either the 10 or 25 c.c. extractor and 50 c.c. for either the 50 or 100 c.c. extractor. An aliquot of the alkaline digest is introduced by pipette into the inner tube. Solvent which is displaced

by the aliquot overflows into the jacket. The column of solvent which remains underneath the aqueous layer is approximately 1 inch deep. The reflux condenser is attached so that its tip touches lightly the funnel of the extractor. The solvent in the jacket is heated rapidly with a coneless but nonluminous flame until returning solvent begins to drain from the extractor. The flame is then regulated so that refluxing continues at a rate which is consistent with a stable interface at the junction of the solvent and sample. Properly digested samples permit the return of solvent at a rate which overflows in a continuous stream. After brief experience with the apparatus, the initial period of heating and regulation of the continuous rate can be accomplished in one or two minutes. The extraction is continued at the steady rate for 15, 15, 30, and 30 minutes for the 10, 25, 50, and 100 c.e. units, respectively.

Transfer of Alkaloid to Acid.—After the extraction is completed, the sample tube is removed from the jacket and set aside. A small funnel is inverted and lowered into the chloroform until it rests on the bottom of the jacket. The stem of the funnel should extend about 2 cm. above the surface of the solvent. A measured quantity of acid is added to the chloroform layer. Either 0.03 N hydrochloric acid, or 0.03 or 0.1 N sulfuric acid, is used, depending on the subsequent procedure which is selected for the analysis. The volume of acid generally equals that of the extracted aliquot, but ratios greater or less than unity are employed when the expected content of the sample indicates any analytic advantage. The condenser is attached again to the jacket and the contents are heated for ten minutes, during which time the funnel actively percolates the chloroform layer through the supernatant acid layer. The condenser is allowed to drain, and any clinging drops on its tip are recovered by tipping against the inner wall of the jacket. The jacket is stoppered tightly with a cork and set aside to cool until the layers are clear and a sharp interface obtains. Aliquots from the acid layer are taken for analysis either by pipetting directly from above the chloroform layer or after separation of the two layers. When pipetting the samples directly, a small mirror is adjusted at 45 degrees in front of the jacket so that the interface is visible and not disturbed by the tip of the pipette.

Determination of Quinine.—The quinine in the acid layer is determined by one or more previously established methods which apply directly to a solution of the alkaloid in either hydrochloric or sulfuric acid. When 0.03 N hydrochloric acid is used in the transfer previously described, the method of Kyker and associates³ is convenient. When the quinine is taken up in 0.03 N sulfuric acid, two methods are directly applicable to the same solution. Either a turbidity of quinine silicotungstate is prepared as previously described³ for hydrochloric acid solutions and measured by an established calibration with an Evelyn photoelectric colorimeter (Table II), or the fluorescence of quinine sulfate, after dilution with 0.1 N sulfuric acid to a suitable concentration, is read against a similar standard solution with a Coleman photofluorometer. For samples of tissue of very low alkaloidal content, 0.1 N sulfuric acid is used in the preceding transfer from chloroform, and the fluorescence of the alkaloid is measured without further dilution.

TABLE II. MEASUREMENT OF QUININE SILICOTUNGSTATE IN 0.03 N SULFURIC ACID

NUMBER OF TRIPPLICATE SAMPLES ANALYZED	EVELYN COLORIMETER READING		QUININE (MG. PER LITER)		
			ACTUAL	OBSERVED	
	RANGE	AVERAGE		RANGE	AVERAGE
6	90.5 to 91.4	91.0	1.0	1.02 to 1.04	1.01
9	78.2 to 79.9	79.3	2.0	1.92 to 2.06	1.98
9	68.6 to 69.8	69.3	3.0	2.93 to 3.06	2.99
9	60.7 to 62.7	61.8	4.0	3.81 to 4.07	3.96
9	54.2 to 56.1	55.2	5.0	4.81 to 5.14	4.96

The results are calculated as follows:

$C = c \times F \times V \times 1000/W$ where

C = mg. quinine per kg. of tissue

c = mg. quinine per liter in the undiluted acid layer

F = factor of dilution, $\frac{\text{total acid layer (c.c.)}}{\text{aliquot of alkaline digest (c.c.)}}$

V = total volume of alkaline digest in liters

W = sample of tissue in grams

STANDARDIZATION

The procedure which is outlined has been verified by repeated extraction and determination of quinine in standard solutions and in samples of urine and tissue from the alimentary tract of the rat. A summary of these data is presented in Table III. A wide variation in the amount of added quinine is covered, the largest being over 3,000 times the smallest. To the biologic

*F, Fluorometric analysis; TS, turbidimetric analysis of silicotungstate.

samples the calculated volume of a concentrated standard solution of quinine dihydrochloride was added by pipette before digestion. The added amounts of quinine which are recorded in Table III pertain to 25 c.c. aliquots which were extracted. Results from larger or smaller samples with extractors of corresponding dimensions are similar in accuracy.

When standard solutions were analyzed, the preliminary digestion of the sample was omitted and aliquots were extracted after adding 50 per cent sodium hydroxide until a concentration of 1 per cent was reached. For urine samples, digestion with 2 per cent alkali for thirty minutes greatly reduced a tendency to emulsify during the extraction. For samples of tissue, the digestion was continued twenty-four hours.

The accuracy of the procedure is best judged by the results in the last column of Table III. This column represents the duplicability which obtains for similar aliquots. The accuracy of the average recoveries which are found in the preceding column is quite satisfactory for biologic studies of quinine. This column entails any errors in the addition of widely varying amounts of alkaloid, as well as those errors which are inherent for the procedure. The average of all recoveries which are listed in Table III is 99.1 ± 0.79 per cent.

APPLICATION AND DISCUSSION

The procedure is especially versatile and efficient in studies where wide variations in the alkaloidal content of the sample occur, such as in a study of the intestinal absorption of quinine at increasing intervals after oral administration. In this connection the method has been used extensively in studies on the rat. The widely used technique of Cori¹⁶ for studying intestinal absorption in small animals does not serve for quinine, since its low solubility at the normal pH of intestinal contents and its tendency to associate with proteins cause it to adsorb on the mucous lining so that the residue cannot be washed out quantitatively. The general application of the method is supported by the work of Alogdelis¹⁷ who used the procedure recently in determining the quinine which remains in the whole body of mice at intervals after oral administration of the drug.

Digestion of a sample of tissue for twenty-four hours may seem a cumbersome step but is recommended on the basis of controlled experiments. Digestion for two hours, as recommended by Kelsey and Geiling,⁴ gave extracts which contained appreciable interfering substances. These substances decreased as the digestion was increased. Slight interference remained after eight hours of digestion. Satisfactory blanks were obtained after twenty-four hours. This specified period is longer than is necessary for some tissues but represents more convenience than periods between eight and twenty-four hours, since the digestion of a series of samples may be begun at a given time on one day and their extraction and analysis at the same time on the following day. No attention is required during the digestion except for the occasional replacing of water which evaporates. If flasks, closed with rubber stoppers which support 10 inch air condensers, are preferred to beakers covered with

watch glasses, very little loss of water occurs. Samples are rendered completely soluble except for fragments of bones and hair which remain when the whole carcass of a small animal is digested for analysis.

During the time in which the procedure was developed, chloroform was not readily available and various grades were used. Irregular periods of good and poor results became correlated with the kind of solvent which was in use. It has been substantiated repeatedly that quantitative recoveries of quinine depend on the use of pure chloroform. Merck's reagent and Baker's CP chloroform yield reliable results. The solvents should be stored in amber bottles in a dark cabinet when not in use. Incomplete and irregular recoveries ranging from 75 to 90 per cent occur when U. S. P. or Technical grades of chloroform from various sources are used. The poor recoveries are more noticeable when the content of the sample is low but persist to some extent at higher concentrations. Some poor grades of solvent did improve but were not entirely satisfactory when fractionated or when washed successively with alkali, acid, and water. Used portions of acceptable solvents remained satisfactory when collected in a storage bottle, washed, dried, and distilled before using again.

In the construction of the apparatus (Fig. 1A) it is essential that the tip of the overflow tube inside the extractor is not fused to the bottom of the latter. Otherwise, pumping of the solvent occurs by forming bubbles of vapor in the overflow tube and the aqueous layer may spill over. Without exception, pumping of the chloroform layer and loss of the aqueous layer has occurred only in those extractors in which this oversight of construction existed. If 1 or 2 mm. intervene the tip of the overflow tube and the bottom of the extractor, the returning solvent from the reflux cools the solvent sufficiently to prevent any boiling inside the extractor due to heating by the rising vapors on the outside.

The maximum volume of an aliquot which is to be used in an extractor of particular dimensions is indicated in Table I. This maximum volume is recommended only for relatively pure aqueous solutions of quinine. The products of digestion of tissue with alkali tend to emulsify slightly at the interface during rapid extraction, so that the sample should not exceed 75 to 80 per cent of the rated capacity of the extractor. No difference is noted in recoveries when as low as 50 per cent of the rated volume of sample is used, since the shorter aqueous layer compensates for the slower turnover in the deeper layer of solvent.

The transfer of the extracted alkaloid to acid may be accomplished without the use of an inverted funnel, which serves as a percolator, if very rapid boiling is maintained so that the two layers appear as one. The percolator permits milder conditions and less chance of loss of the acid layer in the condenser, since with its use less heating with little or no refluxing is sufficient. Also, some delay accompanies the return of a sharp interface when vigorous boiling substitutes for percolation.

The sensitivity and duplicability of turbidimetric measurements of quinine silicotungstate in 0.03 ± 0.002 N sulfuric acid (Table II) compares favorably with the previous use of 0.03 N hydrochloric acid.² When both fluorometric and

turbidimetric determinations are desired on the 0.03 N sulfuric acid layer to which the alkaloid has been transferred, the latter should be run first since it is the less sensitive of the two and serves to indicate accurately the necessary factor of dilution for the application of the former. The lowest level of quinine which is measurable turbidimetrically requires at least a tenfold dilution before fluorometric measurement. Tenfold dilution with 0.1 N sulfuric acid reduces the acidity to 0.093 N. Quinine can be read accurately at this acidity against fluorometric standards which are customarily prepared in 0.1 N sulfuric acid. According to the study by Desha and associates¹⁸ on the effect of hydrogen ion concentration on fluorescence, much greater differences in the concentration of sulfuric acid are permissible between standards and unknowns. Such permissible differences have been confirmed more recently by Valk.¹⁹ Determination of the extracted quinine is not limited to the methods which have been selected in this study, but colorimetric or spectrophotometric methods should be applicable to the extracts.

SUMMARY

A rapid procedure is presented for the quantitative separation of quinine from biologic fluid or tissue by continuous extraction of a digested sample with chloroform. Specially designed apparatus which is simple in construction is described in various dimensions. The extractor represents an interchangeable adaptation of one proposed previously, so that the complete unit permits extraction with solvents of either greater or lesser density than water. The procedure enables the versatile selection of two or more established methods of analysis for simultaneous application to individual samples and stresses the value of this practice in metabolic studies since no specific method is available for quinine. The procedure has proved efficient and convenient during extensive use in animal work.

The authors express their appreciation to the Samuel S. Fels Fund which provided the support for this work.

THE COUNTING OF BLOOD CELLS BY DARK-FIELD ILLUMINATION

GERMAIN CROSSMON, B.S., AND BERNHARDT G. GALLASCH
ROCHESTER, N. Y.

MICROSCOPIC preparations are usually examined by bright-field illumination. The entire field of view is lighted, and preparations to be examined are shown against a light background. Objects are differentiated optically from their surrounding medium by their difference in refractive index, by natural coloration, or by the application of dyes.

In contrast to this is dark-field illumination in which objects appear as self-luminous structures on a dark background. This effect is obtained with the Abbe condenser by placing an opaque stop between the condenser and the source of light so as to exclude the central part of the light rays from the mirror, allowing only an external ring of light to pass to the condenser. The hollow cone of light thus formed illuminates brilliantly any object at its focus, and the object itself reflecting the light into the microscope appears self-luminous on a dark field.

In comparison to light-field, dark-field illumination has had few applications. Perhaps its most important use in medical science is for the detection of motile organisms such as the spirochetes of syphilis and trypanosomes in body fluids. It also should be of value for the enumeration of microscopic objects in counting chambers which, because of their small size, lack of color, or refractive index, are difficult to see with light-field illumination. A few possible applications are the counting of red blood cells, white blood cells, spinal fluid cells, blood platelets, bacteria, yeast, mold, plankton, and dust particles. Although the study of fresh blood cells on thin object slides by dark-field illumination is mentioned in Gage¹ and Gradwohl,² to the best of our knowledge, there is no reference in the literature concerning the counting of blood cells in counting chambers by this method of illumination. This is, no doubt, due to the required object slide thickness necessary for dark field. The object slide with the Abbe condenser and dark-field stop must be approximately 1.3 to 1.4 mm. in thickness, so that the apex of the hollow cone of light can be brought into coincidence with the object. It can be seen readily from the foregoing statement that if relatively thick chambers are used, this hollow cone of light would come to a focal point below the blood cells within the glass counting chamber, and the amount of light thus produced would be inadequate for illumination of the object. The solution to this problem is to increase the focal length of the Abbe condenser by removing its top lens, the numerical aperture of the condenser thus being reduced from 1.25 to 0.30. If the 43X, 0.65 N.A. objective is used, it is necessary also to decrease its numerical aperture by the use of a funnel stop. The method including preferable microscope accessories is described in detail.

From Bausch & Lomb Optical Company.
Received for publication, Nov. 16, 1946.

EQUIPMENT

Although any biologic microscope with Abbe condenser, numerical aperture 1.25, can be used, a binocular medical microscope with 10X paired oculars is suggested for full appreciation of this dark-field method. If increased magnification is desired with the 10X, 0.25 N.A. objective, 15X oculars can be used. The source of illumination must be more intense than usually is required for light-field counting. A microscope lamp using a 115 volt, 100 watt Mazda bulb or a 6 volt, 108 watt ribbon filament bulb and equipment with a Corning Daylite filter and condensing lens furnishes ample illumination for use with either a monocular or binocular microscope. Two dark-field stops, 16 and 20 mm. in diameter, a funnel stop, a hemacytometer, and red and white pipettes complete the essential equipment.

Fig. 1.—Red blood cells as seen with a 10X huygenian eyepiece and a 43X achromatic objective with funnel stop. Three-fourths actual size.

METHOD

The usual dilution fluids, such as Hayem's solution and normal saline for erythrocytes and 1 to 3 per cent acetic acid (tinted with gentian violet) and 0.1 N hydrochloric acid for leucocytes, can be used. However, acetic acid is preferable to hydrochloric since it has a less destructive action on the cytoplasm of the white cells. This difference is more noticeable in dark-field than in light-field illumination. If, as previously recommended, a 115 volt, 100 watt bulb or a

6 volt, 108 watt bulb is used with a binocular microscope, the microscope lamp should be adjusted so as to produce a parallel beam of light. This can be done readily by directing the light beam at a wall at least six feet away and focusing the condensing lens until an image of the source is formed on the wall. The illuminator then can be oriented with reference to the microscope and the beam of light directed at the microscope mirror. A filter should be placed in the holder usually provided with most microscope lamps. This is necessary in order to eliminate all glare from the blood cells and counting chamber, as shown against the dark background. It was found that for this purpose a Corning Daylite filter was superior to the usual combination of a ground glass and blue filter. In order to bring the apex of the hollow cone of light on the blood cells in the counting chamber, the upper element of the Abbe condenser now is unscrewed and removed. A 16 mm. dark-field stop, usually supplied with most microscopes, is placed and accurately centered in the holder provided below the condenser. Using a combination of the low power objective (10X, 0.25 N.A.) and 10 or 15X oculars, the substage condenser now is racked up and down until the counting chamber ruling and blood cells appear white on a black background. It will be found that if the condenser is lowered slightly below this point, a very pleasing illusion of depth is obtained. This effect of depth is appreciated especially in the case of the white blood cells and is of value in distinguishing these cells from possible dust particles that may have been in the diluting fluid or on the counting chamber. If again the condenser is lowered below this point, blood cells appear dark against a light background. Since the counting chamber ruling also is light, this location of the substage condenser is not usually of value.

Dark-field illumination can also be used with the 43X, 0.65 N.A. objective, but its numerical aperture of 0.65 must be reduced by inserting a funnel stop. This stop is standard equipment and, although designed for reducing the aperture of the 97X, 1.25 N.A. objective, it is interchangeable. The size of the dark-field central stop at this magnification should be approximately 20 millimeters. As with the 10X objective, the condenser should be racked up and down until the counting chamber ruling and blood cells appear white on a dark background.

A modified form of dark-field illumination can be obtained by the substitution of Rheinberg color discs for the opaque stops. These discs can be prepared in the laboratory from colorless and red and green-colored gelatin or cellulose acetate, or fixed photographic film can be dyed to the desired shade. The central green disc must be 16 mm. for use with the 10X objective and 20 mm. with the 43X objective. It should be centered and cemented to either an outer colorless or red disc which must be approximately $1\frac{1}{16}$ inches in diameter. Blood cells thus are shown as white objects on a green background when the central green disc is used in combination with an outer colorless disc, and red on a green background when a red disc is substituted for the outer colorless disc. If the latter combination is used, a ground glass filter should be substituted for the Corning Daylite filter. The results obtained are very spectacular but probably have no advantage over the usual dark-field method.

The location of the stops or Rheinberg discs above the lower element of the Abbe condenser will increase the brightness of objects and lines and will add to the ease with which optimum dark-field illumination can be obtained. Since there is no slotted ring provided at this location, it is necessary to construct a holder so designed that the stop or disc is at a location approximately 5 mm. above the condenser. If one expects to do a considerable amount of counting by dark-field illumination, it is believed that the superior results obtained will justify the special construction of the stop holder. The size of the stops or Rheinberg discs in this location should be approximately 13 mm. for the 10X, 0.25 N.A. objective and 16 mm. for the 43X, 0.65 N.A. objective.

SUMMARY AND DISCUSSION

A method has been described for the counting of blood cells in an all glass counting chamber (hemacytometer). This technique, modified as may be necessary, can be used for counting other objects previously mentioned. In order to increase the focal length of the Abbe condenser, 1.25 N.A., the upper lens of the condenser must be removed; if a 43X, 0.65 N.A. objective is used, a funnel stop is necessary to reduce its numerical aperture. Dependent on the location chosen, above or below the condenser, a 13 or 16 mm. stop or disc should be used with the 10X objective and a 16 or 20 mm. stop has proved satisfactory with the 43X objective. The size of the stop for either the 10X or 43X objective is not critical. It is possible that with counting chambers other than those used in this study better results may be obtained with stops slightly smaller or larger than those suggested. The brightness of the counting chamber ruling is dependent on the depth and width of the lines and also on the thickness of the counting chamber. For best results, the over-all thickness of the chamber should be 5 mm. or less and the ruling should be relatively deep and heavy. In place of opaque stops Rheinberg color discs can be used. Blood cells thus are shown as white or red objects on a green background.

CLOROX AND TERGITOL-JAVELLE WATER MIXTURE FOR ACID-FAST BACILLI CONCENTRATION

A COMPARATIVE STUDY

JYUNJI IZUMI
DENVER, COLO.

THE concentrated sputum examination for tubercle bacilli has largely superseded that of the plain smear. Because of the increased numbers of such examinations, a shorter more rapid technique was required. In recent years Clorox¹ has been used as the concentrating substance. Cameron and Castles² found this method superior to that of NaOH-alum and autoclaving methods, and we have similarly been impressed by its value in the past eighteen months. Certain difficulties were encountered, particularly regarding altered staining properties of the tubercle bacilli, rendering the slides difficult to read and interpret. We had previously used a tergitol-javelle water mixture, after its introduction by Petroff and Schain,³ without such difficulties in staining properties. It was decided to evaluate again these two digestants in a parallel series to determine their comparative efficacy.

METHOD OF STUDY

All sputa used in this study were collected routinely in bottles for a twenty-four to forty-eight hour period. After stirring thoroughly with wooden applicators each sputum was divided into two portions. One portion was treated with an equal volume of clorox, stirred with an applicator stick, and centrifuged in 15 c.c. tubes* for ten minutes at 2,200 r.p.m. The clorox sputum mixture was not allowed to stand longer than ten minutes prior to centrifugation, as it was found that prolonged exposure (twenty minutes or more) rendered some organisms nonacid-fast or markedly impaired their staining properties. After decanting the supernatant fluid the centrifuge tubes were inverted for fifteen to twenty minutes over absorbent paper to allow for maximum drainage. The sediment was smeared and then stained by the Ziehl-Neelsen method.

The other portion of each sputum was treated with tergitol-javelle water mixture. This digestant was prepared in the manner recommended by Petroff and Schain.³ Equal volumes of this digestant and sputum were mixed and agitated periodically with applicator sticks until digestion was completed. The incubation period employed by Petroff and Schain was omitted in this series. Digestion usually was completed within a few minutes. Some specimens, however, were very resistant and required as long as thirty minutes for homogenization to occur. Centrifugation was done in the same manner as employed in the clorox series. The decanted tubes were inverted over absorbent paper for fifteen to thirty minutes, a longer time being required in some cases to obtain maximum drainage. The smeared slides were stained in the previously mentioned manner.

No slide was considered negative until well over 100 fields had been examined. The method of reporting positive slides was based on the recommendation of the American Trudeau Society,⁴ which is as follows:

From the National Jewish Hospital.

Received for publication, Nov. 19, 1946.

*Sixteen-place, type 2, International Centrifuge.

Numerous (+++): Ten or more acid-fast bacilli in most oil immersion fields

Few (++) : Single acid-fast bacillus found in most oil immersion fields

Rare (+): Single acid-fast bacillus found in occasional oil immersion fields

In the case of 1 plus slides the number of bacilli found in the field examined were recorded.

RESULTS OF THE STUDY

In the course of this study 171 sputum specimens were examined. One hundred specimens were found to be negative by both methods; seventy-one were found to be positive by one or both methods. The method employing tergitol-javelle water mixture gave eleven more positive slides than did the clorox method (Table I). With the method employing tergitol-javelle water mixture, 42 per cent of the slides were positive for tubercle bacilli. By the clorox method only 35 per cent were found positive. Thus the method using tergitol-javelle water mixture was superior by 7 per cent to the clorox method.

TABLE I. TOTAL NUMBER OF POSITIVE AND NEGATIVE SLIDES

NUMBER OF SPUTA EXAMINED	TERGITOL-JAVELLE WATER MIXTURE		CLOROX	
	NEGATIVE	POSITIVE	NEGATIVE	POSITIVE
171	100 (58%)	71 (42%)	111 (65%)	60 (35%)

TABLE II. COMPARISON OF DEGREE OF POSITIVITY WITH BOTH METHODS

NUMBER OF POSITIVE SLIDES	TERGITOL-JAVELLE WATER MIXTURE			CLOROX		
	+++	++	+	+++	++	+
71 (Total positive specimens)	19	23	29	10	21	29
60 (Positive by both methods)	19	23	18	10	21	29

In Table II the breakdown of the positive slides into the degree of positivity is recorded. It is to be noted that there is a decided shift to lesser degrees of positivity with the clorox method.

In those specimens found to be 1 plus by both methods (nineteen cases), slightly over twice as many organisms were found per 100 fields by the method using tergitol-javelle water mixture as with the clorox method (Table III).

TABLE III. COMPARISON OF NUMBERS OF BACILLI IN 1 PLUS SLIDES (NINETEEN CASES)

METHOD	TOTAL FIELDS EXAMINED	NUMBER OF BACILLI FOUND IN FIELDS EXAMINED	AVERAGE NUMBER OF BACILLI PER 100 FIELDS
Tergitol-javelle	745	92	12.4
Clorox	1,108	57	5.1

CONCLUSION AND SUMMARY

One hundred seventy-one sputum specimens were examined by both the clorox and the tergitol-javelle water mixture methods. Out of a total of seventy-one positive specimens the method using tergitol-javelle water mixture gave more positive results and exhibited better ability to concentrate the bacilli than did the clorox method. The treatment of the acid-fast bacilli with the mixture of

tergitol-javelle water does not show the impairment in staining that occasionally occurs when treated with clorox. For these reasons it was decided to abandon the use of clorox in favor of tergitol-javelle water for concentration purposes.

The writer wishes to express his appreciation to Dr. Allan Hurst for suggesting this study and for the aid received in the preparation of this paper.

MICROPRECIPITATING UNIT FOR BLOOD AND TISSUE PROTEINS

ARNOLD LAZAROW, PH.D., M.D.

CLEVELAND, OHIO

IN THE course of microanalysis of blood and tissues it is often necessary to precipitate proteins. This is usually done by mixing the blood and the protein-precipitating fluid, placing the mixture in a capillary tube, sealing, and centrifuging. The supernatant fluid is finally separated from the precipitate by cutting the tube just above the level of the precipitate. The method described in Methods enables one to carry out all operations within the same pipette. The drawing of blood and the precipitation of proteins can easily be done in a patient's room, and the tube can be set aside for centrifuging upon return to the laboratory.

METHODS

The pipette* illustrated in Fig. 1 consists of a capillary tube used for measuring the blood and a diluting bulb whose volume is equal to five or ten times that of the capillary tube. The bulb end is sealed to a standard taper male joint and is fitted with a standard taper cap. Rubber bands placed on the hooks serve to hold the cap in place during centrifugation. Blood is drawn into the

Fig. 1.—Top, a blood-precipitating pipette fitted with standard taper joint and cap. Bottom, a standard taper female-female adapter.

pipette to the 20 c.mm. mark. The protein-precipitating fluid is then drawn into the pipette to the 240 c.mm. mark. After mixing, a drop is blown out of the pipette to remove the unmixed protein precipitating fluid which is present within the capillary portion of the pipette. The cap is put on and fixed in position with a rubber band; the pipette may be put aside for a time at this stage. After centrifugation at appropriate speed, the cap is removed.

From the Department of Anatomy, Western Reserve University School of Medicine, Cleveland, Ohio, and the Marine Biological Laboratory, Woods Hole, Mass.

Received for publication, Nov. 12, 1946.

*The pipette was made by James D. Graham, University of Pennsylvania School of Medicine, Philadelphia, Pa.

The volume of the cap is arranged so that all the precipitate can be contained within the cap, the pipette proper containing only blood filtrate. If the volume of the cap is 2.25 times that of the blood used, the cap will contain all the blood precipitate when tungstic acid is used as the precipitating agent. If a 5 per cent solution of trichloroacetic acid is used, the volume of the cap should equal the volume of blood used. The female-female adapter shown in Fig. 1 is used in place of the cap to transfer the blood filtrate to the microcolorimetric reaction-vessel described in another paper (page 215).

If the precipitate is desired, the remaining supernatant fluid in the cap can be drawn off with a capillary tube and the precipitate can then be removed from the cap.

A SIMPLE APPARATUS FOR QUANTITATIVE MICROCOLORIMETRIC ANALYSIS IN FINAL VOLUMES OF 0.15 c.c.

ARNOLD LAZAROW, PH.D., M.D.
CLEVELAND, OHIO

LOWRY and Bessey¹ have reported that accurate measurements may be made in the Beckman spectrophotometer, on volumes of 0.1 c.c., by using a special colorimeter cell. I have found also that the Lumetron photoelectric colorimeter could be used for this purpose if it were equipped with a galvanometer of the multiple reflection type. Special 10 by 3 mm. cells were used. White blood cell diluting pipettes were used for carrying out the colorimetric reactions.

The technique described herein simplifies the microcolorimetric procedures. All volume measurements, heating, and color development can be carried out within one tube.

APPARATUS

A tuberculin syringe (1 c.c. with graduations of 0.01 c.c.) is used to control the volume within the reaction pipette. To facilitate smooth operation the plunger is fitted with a spring clip. A Shick-Vim syringe can be used in place of the tuberculin syringe. A convenient reaction-vessel* for microcolorimetry (Fig. 1) consists of a capillary tube with a capacity of 30 c.mm. and a dilution bulb whose volume is 150 c.mm. The capillary tube, which must be of constant internal diameter, is graduated into 50 or 100 divisions, so that fractional volumes may be measured. The bulb end of the pipette is fitted with a standard taper female joint,† whereas, the pipette end is fitted with a standard taper male joint. A standard taper cap fits over this pipette end for sealing. A glass bead sealed in the mixing bulb facilitates mixing.

The pipette and syringe are mounted by clips at about a 30 to 45 degree angle (Fig. 2). A three-way spinal puncture stopcock (Yale B-D L/S 2) is placed between the syringe and the reaction pipette. The purpose of this stopcock is to facilitate removal and replacement of a partially filled reaction pipette from the syringe. When reinserting a partially filled reaction pipette into the stopcock, the latter should be open to permit flow of air from the side tube; otherwise fluid may be forced out of the tip of the pipette as it is inserted into the stopcock. With the pipette in place, however, the stopcock should be turned so that the pipette communicates only with the syringe.

The joints should be greased and the syringe oiled to prevent leakage of air into the system.

From the Department of Anatomy, Western Reserve University School of Medicine, Cleveland, Ohio, and the Marine Biological Laboratory, Woods Hole, Mass.

Received for publication, Nov. 19, 1946.

*The reaction-vessel was made by James D. Graham, University of Pennsylvania School of Medicine, Philadelphia, Pa.

†Because of greater simplicity of manufacture, the pipette now supplied by J. D. Graham is fitted with a male joint at the bulb end and a male-female adapter inserted on the three-way stopcock.

Fig. 1.—Microcolorimetric apparatus; the microcolorimetric reaction-vessel is inserted into a three-way standard taper lumbar puncture stop-cock; a tuberculin syringe attached to the stopcock permits a delicate control of volume.

Fig. 2.—Apparatus mounted.

A vessel for the addition of reagents is shown in Fig. 3. It has a bulb containing about 5 c.c. and is fitted with a standard taper female joint and a stopcock to control the fluid in the bulb.

FIG. 3.—Reagent-addition vessel.

METHODS

In carrying out the colorimetric procedure blood filtrate or tissue extract is placed in the reaction-vessel. For this purpose the female-female adapter is placed on the male joint of the blood-precipitating pipette described in another paper² (page 213), and this in turn is connected with the reaction-vessel. The blood filtrate is drawn into the tube a little past the 15 c.mm. mark, because removal of the blood precipitating pipette causes the level of liquid in the colorimeter reaction tube to change slightly. By means of the syringe, the volume is adjusted to exactly the 15 c.mm. mark. A small bubble of air is then drawn into the capillary in preparation for adding the next reagent. If blood sugar were being determined by the Folin-Malmros³ method, one volume of alkaline ferrieyanide solution would be added next. For this purpose the reagent-addition vessel (Fig. 3) is connected to the male joint of the reaction-vessel. The stopcock is opened and by means of the syringe the liquid is drawn into the pipette slightly above the 15 c.mm. mark. The stopcock connecting the syringe and the reaction-vessel is closed, the stopcock of the reagent-addition vessel is closed, and then the latter vessel is removed. The three-way stopcock

that connects the syringe and the pipette then is opened, the volume is adjusted to exactly 15 c.mm., and the alkaline ferrieyanide solution is drawn into the bulb. Mixing with the blood filtrate can be accomplished by alternately forcing the liquid into the pipette and drawing it back into the bulb. A cap is placed on the male joint of the reaction-vessel, and this is secured in place with a rubber band; the vessel then is removed from the stopcock. Further mixing can be accomplished, if desired, by rotating the pipette while in a vertical position. (The pipette must not be inverted, for if the fluid reaches the upper capillary, later dilutions cannot be made with great accuracy.) The tubes are placed, at an angle of 30 to 45 degrees, in a water bath designed to heat only the bulbs of the pipette. If the cap and capillary portion of the pipette are also heated, the air within them expands and forces its way out past the liquid in the bulb and then out the bulb end. On cooling, however, the air contracts and the liquid is sucked from the bulb into the capillary and cap.

After cooling, the pipette is replaced upon the stopcock, the cap is removed, and two volumes of a solution of ferric gum ghatti are measured and then sucked into the bulb. The cap is reinserted, the pipette is removed from the rack, and the contents are mixed by rotation in the vertical position. After standing twenty minutes, the reaction-vessel is replaced, distilled water is added to the 180 c.mm. mark, and the contents of the bulb are mixed by shaking. The drop of water contained in the capillary tube is blown out. Then an adapter is inserted on the male joint, the contents are transferred to a microabsorption cell, and the extinction is measured in a photoelectric colorimeter.

DISCUSSION

By using standard methods and a volume of 150 c.mm., a large number of colorimetric procedures can be carried out on samples of tissue weighing only 1 mg. or on a few cubic millimeters of blood. The procedure is simple and could be employed routinely in the determinations customarily carried out in the clinical laboratory. It should prove especially useful in pediatric practice, since a few cubic millimeters of finger blood will prove sufficient for most chemical procedures.

If 50 c.mm. (about 1 drop) of blood are available for chemical analysis, the final volume for colorimetry need not be limited to 0.15 c.c. but can be carried out on final volumes of 1.0 cubic centimeter. Sufficient blood filtrate is obtained from one drop of blood to carry out several chemical determinations. By applying the technique used by Shock and Hastings,⁴ it should be possible to substitute a sector of a regular cylinder for part of the bulb, and in this case the pipette itself could be used for the colorimeter tube. The volumes of the colorimetric reaction—vessel may be reduced if desired for only 50 c.mm. are required for use with the Beckman microcells.

The accuracy of this procedure has been found to approach that of ordinary macrocolorimetric procedures. Inasmuch as all volumes are measured within the same pipette, it is necessary only to determine the dilution-factor of the bulb for each pipette. This can be done simply by measuring 15 c.mm. of a known colored solution in the pipette, diluting it to 180 c.mm. and mixing. The

Distilled water contained in the capillary is blown out and the contents of the bulb are then placed in the microabsorption cell. The transmission of light is measured and the precise dilution of the 15 c.mm. is thus determined in the pipette under the conditions of use. The absolute volume of a given pipette makes relatively little difference in the determination.

The microcolorimetric procedure can be carried out as rapidly as an ordinary macroprocedure. The small amount of blood required (finger puncture), the simplicity of the method, and the economy of table space and dish washing—all serve to make this procedure highly desirable in ordinary clinical chemistry. This technique should be most useful in special research projects where only small amounts of material are available.

SUMMARY

A simple apparatus is described which is useful in colorimetric analysis employing small final volumes (0.15 c.c. or less). Samples of blood or other tissues of 0.001 c.c. or 1 mg. are adequate for most colorimetric procedures using this technique.

BOOK REVIEWS

Penicillin—Its Practical Application. Edited by *Sir Alexander Fleming*, M.B., B.S., F.R.C.P., F.R.C.S., F.R.S., Professor of Bacteriology, the University of London, St. Mary's Hospital, London. The Blakiston Company, Philadelphia, 1946. Price \$7.00. Cloth with 380 pages, 59 illustrations.

Since all of the twenty-eight contributors to this book, prepared under the editorship of Sir Alexander Fleming, are British, it constitutes a useful compendium of the investigative work and clinical applications of penicillin by British workers, much of which may not be familiar to American physicians.

The first section, totaling 104 pages, is devoted to the general aspects of the subject and consists of six chapters on the history and development, chemistry and manufacture, pharmacy, pharmacology, bacteriological control, and methods of administration of penicillin. It is needless to state that the chapter on the history and development of the compound, written by Fleming himself, is outstanding. The chapter on the chemistry and manufacture of penicillin is likewise comprehensive, although the different penicillins (F, G, X, and K) are but barely mentioned and much of the space, with numerous illustrations, devoted to methods of manufacture could have been better expended on more comprehensive discussions of the pharmacology and bacteriological aspects of the subject in view of their greater clinical importance. The pharmacy of penicillin is devoted exclusively to methods employed by the British Pharmacopoeia, and while Fleming adequately describes his own methods for the detection and assaying of penicillin in the blood, urine and other body fluids, the Oxford cup and various serial dilutions methods are so briefly and inadequately described as to be of but little or no value to laboratory workers. One may also regret that so little is given on the antimicrobial activity of penicillin *in vitro* and *in vivo* or likewise, on the subjects of natural and so-called acquired resistance of bacteria to penicillin, with methods for determining the susceptibility of organisms to the compound *in vitro* which are so important in relation to penicillin therapy.

The second section, 21 chapters totaling 257 pages, is devoted to the clinical aspects of penicillin in the prophylaxis and treatment of disease. Some of these chapters, especially those devoted to the prophylactic use of penicillin, the treatment of wounds and gangrene and the treatment of dental and oral infections, are satisfactory. All of the chapters summarize the clinical experience of British physicians and surgeons, and some diseases are discussed in a very superficial fashion due to a lack of experience; this is especially true of the venereal diseases and particularly of syphilis. Since the book was written by a large group of contributors, there is much useless duplication of material with special reference to methods of administration. For example, there is a chapter on chest infections and another on chest surgery which could have been combined; likewise, there is a chapter on orthopaedic surgery and fractures and another on osteomyelitis which could also have been advantageously combined. Why a chapter on penicillin and the general practitioner was included is difficult to understand, particularly because of its sketchy character and the fact that practically all of the material is covered in other chapters.

While references to the literature of American contributions to penicillin are no slighted, the value of the book from the reference standpoint is sharply limited. Thus the chapters on penicillin in the treatment of chest infections and on the treatment of brain and meningeal infections have no references at all, those on methods of administration and on orthopaedic surgery and fractures have but one each, that on the chemistry and manufacture of penicillin only two, and that on hand infections only three.

Modern Development of Chemotherapy. By *E. Havinga, H. W. Julius, H. Veldstra, and K. C. Winkler.* Elsevier Pub. Co., Amsterdam-New York, 1946. Price \$3.50. Paper with 175 pages.

In spite of the ever-growing burden of oppression and starvation in Holland due to the recent war, research was continued intensively in all directions. Some of the results were published in Dutch periodicals but most of them, for obvious reasons, were kept a secret during the war. The present monograph is one of a series summarizing this research work in different fields now being published, with the hope that they will further intensify the interest shown by the allied nations in the Netherlands and the whole-hearted preparedness of this courageous nation to contribute to the progress of mankind.

The present monograph clearly and concisely summarizes the investigations of Havinga and Veldstra in Amsterdam and of Julius and Winkler in Utrecht on the following: The mechanism of action of the sulfonamide compounds and p-aminobenzoic acid; chemical investigations on the synthesis and activity of sulfonamide derivatives and of related compounds; pharmacological, immunological, and clinical investigations on sulfonamide compounds; as well as a brief chapter bearing upon investigations on antibiotic agents in mycotherapy, with special reference to expansine. Foreign literature is referred to only in so far as it has a direct bearing on the Dutch research work.

JOHN A. KOLMER, M.D.

Renal Hypertension. By *Eduardo Braun-Menendez, Juan Carlos Fasciolo, Luis F. Leloir, Juan M. Munoz, and Alberto C. Taquini,* Institute of Physiology, Faculty of Medical Sciences, and Institute of Cardiology, V. F. Greg Foundation, Buenos Aires, Argentina. Translated by *Lewis Dexter, M.D.,* Harvard Medical School and Peter Bent Brigham Hospital, Boston, Mass. Charles C Thomas, Publisher, Springfield, Ill., 1946. Price \$6.75. Cloth with 451 pages.

The authors' purpose is to describe and evaluate studies in experimental hypertension made during the past fifteen years. Topics such as the production of hypertension in animals, the renal vasopressor system, the roles endocrine and nervous influences play, and the possible correlations with hypertension in human beings are considered at length. An excellent bibliography follows.

The reviewer does not believe that present evidence justifies the strong views advanced by the authors on many points.

Thus, renal ischemia is apparently accepted as the initiating and common factor in experimental, renal, and clinical hypertension, although a close reading of the text shows no thoroughgoing proof of the assumption but a good deal of evidence to the contrary. The morphologic evidence that early in the disease hypertensive renal arteriolar sclerosis is often absent is disregarded, so the facts are whipped into a sort of ischemic party line. The authors subscribe to the notion that angiotonin (hypertensin) is the cause of the rise of arterial pressure in experimental and clinical hypertension. In so doing they necessarily underemphasize the failure to demonstrate such a substance in the blood of hypertensive dogs or human beings.

Examples can be multiplied and only serve to show that this field of investigation is far from static. Since the authors' assurance is not shared by most investigators, their statements might well mislead those introduced to the subject by a reading of this book. Expression of emotional preferences perhaps too often occurs for writing of this sort.

The book is well made and the translation good. It is recommended as a reference text for those engaged in the study of experimental renal hypertension.

ROBERT BIRCHALL

Peripheral Vascular Diseases. By *Edgar V. Allen*, B.S., M.A., M.D., M.S. in Medicine, F.A.C.P., Division of Medicine, Mayo Clinic, Associate Professor of Medicine, Mayo Foundation, Graduato School, University of Minnesota, Diplomate of the American Board of Internal Medicine; *Nelson W. Barker*, B.A., M.D., M.S. in Medicine, F.A.C.P., Division of Medicine, Mayo Clinic, Associate Professor of Medicine, Mayo Foundation, Graduato School, University of Minnesota, Diplomate of the American Board of Internal Medicine; and *Edgar A. Hines, Jr.*, M.D., B.S., M.A., M.S. in Medicine, F.A.C.P., Division of Medicine, Mayo Clinic, Associate Professor of Medicine, Mayo Foundation, Graduato School, University of Minnesota; with Associates in the Mayo Clinic and Mayo Foundation. W. B. Saunders Company, Philadelphia, 1946. Price \$10.00. Cloth with 871 pages and 386 illustrations.

This book is by far the most extensive on peripheral vascular disease which has been published. There is a thorough review of what is known of disease affecting peripheral arteries, veins, and lymphatics. However, hypertension and vascular diseases of the central nervous system have not been treated because they are considered as special subjects and are beyond the scope of the present work.

Well-documented pathologic and clinical descriptions, supplemented by discussions of pathologic physiology, are offered for each vascular disease. Chapters on nailfold capillaries, the physiologic significance of sweating, the scalenus anticus syndrome, glomus tumors, and others were contributed by other authors. These chapters broaden the entire work. The surgical treatment of certain peripheral vascular diseases is considered in the final chapter. The medical treatment of such disorders is extensively reviewed. In the preface the authors stated that they would not hesitate to express their own opinions, particularly regarding controversial points of therapy. In what is largely an impartial review of this subject, it seems that their reasons for rejecting certain forms of treatment are usually made clear.

The book will largely fulfill its two goals, to aid the physician and student in the study and care of patients with peripheral vascular disease and to emphasize that "there remains a vast and fruitful field for research in peripheral vascular diseases."

JOHN R. SMITH.

BLOOD TRANSFUSION STUDIES

III. THE RELATIONSHIP OF HEMOGLOBINEMIA AND OF THE PH OF THE URINE TO RENAL DAMAGE PRODUCED BY INJECTION OF HEMOGLOBIN SOLUTIONS INTO DOGS

EDMUND B. FLINK, M.D.

MINNEAPOLIS, MINN.

HEMOGLOBINURIA occurring after hemolytic transfusion reactions has been a major problem in the use of whole blood transfusions since their inception. In 1667 Jean Baptiste Denys¹³ first described the sequelae of a transfusion of incompatible whole blood (sheep blood). It is well known that serious reactions still occur after transfusion in spite of tests for compatibility, etc. There have been a large number of reports of anuria and death from transfusions since 1900. Hesse⁵⁰ received answers to questionnaires sent to 1,700 clinics and hospitals all over the world. Two hundred seventeen cases of hemolytic shock following transfusions were reported. Out of 200 cases in which definite statements were made as to the outcome, 105 of the patients died, or a mortality rate of 52 per cent. Other authors^{13, 21, 45, 68} have reported small series of cases with comparable mortality rates. Hesse⁴⁹ also summarized the information available on the use of universal donors blood in the transfusion of patients of other groups and found twenty deaths occurring in a series of forty-eight reactions. Other isoagglutinins such as the anti-Rh agglutinin were not excluded in this group of cases, so high titers of agglutinins in the donors plasma cannot be incriminated in all of these cases. Hardin⁴⁷ compared two series of transfusions in the Army Medical Service. There was no difference in the reaction rates between the 7,299 transfusions of group specific blood and the 9,392 transfusions of universal donor blood. Blackwater fever is the most important cause of death of all patients with hemoglobinuria, for there are a large number of cases each year in tropical areas, and the mortality rate is approximately 25 per cent.^{35, 65, 79} Recovery from either condition may occur after virtual anuria or oliguria of as much as a week's duration.^{8, 15, 20, 31, 41, 45, 56, 66, 68, 82}

Pathology of the Renal Lesion in Clinical Hemolytic Conditions.—The mechanism of renal damage has been the subject of many pathologic studies in the past. Werner⁸⁸ and Barratt and Yorke⁸ demonstrated that the kidneys of patients dying from blackwater fever contained granular material in the lumina of the tubules and attributed the urinary suppression to mechanical blockage of the tubules. Ayer and Gauld,⁵ Baker and Dodds,^{6, 7} Bordley,¹³ Daniels and associates,²¹ DeGowin and co-workers,²²⁻²⁴ Goldring and Graef,⁴⁵ and Lindau⁶⁰

From the Department of Internal Medicine of the University of Minnesota.

The subject matter is taken from a thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

Aided by a grant from the Minnesota Society of Internal Medicine.

Received for publication, Jan. 31, 1947.

have contributed much to the study of clinical cases of hemolytic transfusion reactions and the pathologic study of the renal damage produced. Very little attention has been given to hemoglobinemia. More surprising still, hemoglobinuria itself is not mentioned in some cases and is mentioned in a cursory manner in most reports.

The renal lesions after transfusion reactions have been compared with those in other hemoglobinuric states, namely, blackwater fever,^{8, 90} acute hemolytic anemias from drug administration,^{37, 83} burns,⁸¹ and crush injuries.¹⁶ March hemoglobinuria,⁴⁴ paroxysmal nocturnal hemoglobinuria,^{46, 52} and paroxysmal cold hemoglobinuria⁶⁴ usually do not cause renal damage. Possible explanations for this will be discussed later. DeGowin and co-workers,^{22, 24} Lindau,⁶⁰ Bordley,¹³ and others^{18, 21, 45, 74, 83, 90, 92} agree in all essential details about the pathologic findings. There are degenerative changes in the tubular epithelium, especially of the loops of Henle and distal convoluted tubules, interstitial edema in the corticomedullary portion, granules of hemosiderin in the cytoplasm of the cells of the proximal and distal convoluted tubules, and the appearance of a variable number of deeply pigmented casts in the lumina of the loops of Henle, distal convoluted tubules, and the collecting tubules. The degenerative tubular changes vary from mild vacuolization to necrosis and desquamation of cells. Calcium deposits in the degenerated tubules and definite signs of regeneration of epithelial cells have been found.⁴⁵

The importance of the pigment casts has been a major point of dispute among students of the pathology of transfusion reactions and blackwater fever. Baker and Dodds⁶ are of the opinion that the casts cause obstruction of the individual nephron and, hence, cause renal insufficiency. Many other investigators^{55, 74, 85, 91, 92} agree with this concept, but there are some who believe that the cast formation is only secondary to the tubular epithelial degeneration and not the cause of renal insufficiency.^{5, 25, 45, 60} In their study of nine cases DeGowin and co-workers²⁴ concluded that several patients had evidence of renal tubular obstruction sufficient to cause uremia but that most patients had evidence of tubular epithelial cell necrosis and interstitial edema as the predominant lesion. Thus, they thought that there are several factors which operate in cases of hemolytic transfusion reactions in human beings. Others^{13, 18, 21} have also taken this intermediate position.

The liver is likewise involved in cases of hemolysis from any cause.^{45, 60} There is a variable amount of central necrosis of the lobules of the liver. In some cases of blackwater fever and of transfusion reaction this is very severe, with the pathologic appearance of acute atrophy of the liver. The reticulo-endothelial cells of the spleen, liver, and lymph nodes contain a large number of hemosiderin granules.

Experimental Production of Renal Damage by Injection of Hemoglobin Solutions.—Many attempts to reproduce the renal damage in experimental animals have been partially or completely successful. Ponfick⁷⁶ in 1875 was the first one to attempt to reproduce the lesions occurring in blackwater fever. He found that the injection of heterologous blood into dogs, cats, and rabbits resulted in hemoglobinuria and the deposition of pigmented casts in the tubules of

the kidney. Levy⁵⁹ injected pure hemoglobin solution and both homologous and heterologous blood cells into rabbits. He observed that the epithelium of the proximal convoluted tubules became swollen but retained its staining quality. Casts appeared in the loops of Henle and the collecting tubules. In some tubules the epithelium was entirely denuded.

Yorke and Nauss⁹⁴ injected homologous hemoglobin solution into rabbits and found that unless the rabbits had been taking a dry diet before the injection and unless the hemoglobin solution was concentrated anuria did not occur. The largest dose used by them was 13 Gm. at a single injection. The renal pathology was reported to be like that of blackwater fever resulting in urinary suppression. Barratt and Yorke⁵ showed that if hemolyzed blood were centrifuged to remove the stroma of the red cells much larger amounts were then tolerated by rabbits. Sudden death resulted during or immediately after injection when the stroma was not removed. Other authors^{6, 12} have had similar experiences. Levy,⁵⁹ however, was unable to produce any renal lesions by injecting erythrocyte stroma alone.

Baker and Dodds⁶ reported results of three rabbit experiments and gave very incomplete protocols as to dose, pH of urine, and details of pathology. When the injected rabbits were getting a diet with an acid ash, they found that the urine was brown in color and contained much sediment; however, when the rabbits were getting an alkaline ash diet of green vegetables, the urine was red and clear. The acid urine contained methemoglobin and oxyhemoglobin, but the alkaline urine contained only oxyhemoglobin. They concluded that intravascular hemolysis resulting in suppression of urine caused blockage of the renal tubules only when the urine is acid.

DeGowin and co-workers^{23, 24} injected hemolyzed dog erythrocytes into a number of dogs under various experimental conditions. Some of the dogs were fed an alkaline ash diet and the others a cooked meat diet with 8.0 Gm. of ammonium chloride daily. The doses of hemolyzed erythrocytes were measured in terms of the volume of packed red blood cells (unwashed) and ranged from 3.0 to 35.0 c.c. per kilogram of body weight with an average of 10 c.c. per kilogram. When the urine was alkaline, four dogs received thirty-two transfusions of more than 10 c.c. of hemolyzed red blood cells per kilogram but did not develop fatal renal insufficiency; however, when the urine was acid, seven out of twelve dogs given comparable doses of hemolyzed blood cells died of uremia, frequently with terminal rigidity and convulsions. Three died after a single transfusion, and four dogs died from uremia after an injection of 9.5 to 10 c.c. of hemolyzed packed red blood cells per kilogram. DeGowin and co-workers also gave small doses of hemoglobin (2 c.c. of packed cells per kilogram body weight) daily for thirteen days to a dog with acid urine and to one with alkaline urine; they found no evidence of renal damage in spite of continuous hemoglobinuria. The kidneys of the dogs dying from uremia had many large casts in the loops of Henle and distal convoluted tubules and degeneration or necrosis of the tubular epithelium in some areas. Several of the dogs with neutral or alkaline urine during injections were sacrificed when in good health. There was no evidence of cast formation or damage to the renal epithelium in these dogs.

Wakeman and associates⁵⁵ were able to produce anuria and death in dogs by intraperitoneal injections of large doses of hemoglobin solutions. The pathologic appearance of the kidney was similar to that noted by DeGowin and co-workers. Many others have failed to produce renal damage but have used much smaller doses and have paid little or no attention to this fact. Foy and associates⁴⁰ have criticized DeGowin's work stating that extrarenal factors of dehydration, hypochloremia, or acidosis probably accounted for the results obtained in acidified animals. However, DeGowin and co-workers specifically state that their animals were maintained in good condition on the acid diet for months without losing weight and that the carbon-dioxide combining power and plasma chloride levels were within normal limits before injecting hemoglobin solutions. The vomiting occurred only after animals had been injected. Some of these animals developed hypochloremia and alkalosis from vomiting after uremia had set in. In one of Bordley's cases¹³ hypochloremia was not a feature in spite of the development of uremia. DeGowin and Baldrige²² found normal carbon-dioxide combining power and chloride concentrations in their patients at the time of transfusion reactions. In the clinical history of patients with urinary suppression due either to transfusion reaction or to blackwater fever, the oliguria or anuria usually developed before any dehydrating factors such as vomiting could occur. A patient with blackwater fever reported by Wakeman and associates⁵⁵ had moderate depletion of chlorides on the day following development of hemoglobinuria. Nausea and vomiting in this patient were severe.

Bing¹¹ used solutions of oxyhemoglobin and methemoglobin made from crystals of the respective pigments instead of hemolyzed blood cells as used by most other investigators. However, the largest dose of hemoglobin used was 13.0 Gm., or a dose about one-third of the average amount used by DeGowin. Bing made a careful study of tubular and glomerular function. He was able to produce profound renal damage in dogs rendered acidotic by large doses of ammonium chloride following injection of 3.5 to 13.5 Gm. of methemoglobin solutions. Marked tubular damage and only rare pigment casts were observed microscopically in the kidneys of these dogs. Dogs with a normal alkali reserve did not develop any decrease in renal function when 5.5 to 8.1 Gm. of methemoglobin were injected. No decrease in function was observed in either normal or acidotic dogs when oxyhemoglobin solutions were injected. Bing produced an actual acidosis and not just an acid urine.

Aubertin and co-workers^{4, 58} were able to produce varying degrees of renal insufficiency in dogs by the injection of varying doses of hemoglobin solutions after preliminary bleeding of the dogs. The largest doses uniformly caused severe renal injury or death from anuria. Those dogs with transient oliguria recovered completely, while those with longer-standing oliguria developed chronic renal insufficiency and death. In the pathologic material they found many pigment casts and were thus led to stress the obstruction of the tubules. Epithelial degeneration occurred also. No attention was given to the reaction of the urine.

The Mode, Site, and Amount of Hemoglobin Excretion by the Kidney.—Many investigators have studied the mode and site of excretion of hemoglobin by the kidney and the renal threshold for hemoglobin in man and experimental animals. Bieter¹⁰ showed that hemoglobin was not excreted by the aglomerular toadfish but was excreted by the catfish and the eel in comparable doses. Doubling the dose of hemoglobin failed to produce hemoglobinuria in the toadfish. Albuminuria could not be produced in the toadfish either. Webster and associates⁸⁶ were unable to produce hemoglobinuria in frogs by perfusing the renal portal system with hemoglobin solution, but they were able to produce it by perfusing the aorta of the same frog preparations. Newman and Whipple⁷⁰ showed that repeated injections of hemoglobin in doses below the minimal renal threshold for excretion resulted in no deposit of iron pigment in the convoluted tubule cells. Lison⁶¹ injected hemoglobin solution directly into the tubule lumen and found absorption of the hemoglobin granules into the tubule cells. He also ligated the renal artery of frogs and injected hemoglobin solution. No hemoglobin was excreted by the kidney and no granules of pigment appeared in the tubule cells. Yuile⁹⁶ agrees that hemoglobin escapes only by way of the glomerulus. The renal thresholds for hemoglobin can be explained on the same basis as thresholds for glucose and other substances, namely, that the tubule cells reabsorb all hemoglobin excreted up to a certain level.

Monke and Yuile⁶⁹ determined the simultaneous plasma clearance rates for creatinine and hemoglobin when plasma hemoglobin concentrations were about 250 mg. per cent. Hemoglobin clearance was found to be 3 per cent of that of creatinine. They found renal thresholds in a large series of dogs to vary from 80 to 150 mg. per cent. Yuile and Clark⁹⁸ also determined the myohemoglobin clearance rate and found it to be 55 to 60 per cent of that of creatinine. The difference can be explained on the basis of the molecular weight of the two hemoglobins. Myohemoglobin has a molecular weight one-fourth of that of hemoglobin, or approximately 17,000. Monke and Yuile⁶⁹ postulate that only 3 per cent of the glomerular pores are electrostatically large enough to allow the escape of the hemoglobin molecule. The uniformity of the process indicates that it is not a matter of glomerular injury.

The threshold for hemoglobin has been determined in human subjects a number of times. Sellards and Minot⁸⁰ showed that injection of hemoglobin solution into human subjects could be carried out without untoward reactions. They used as much as 33 c.c. of packed red blood cells hemolyzed with distilled water. Gilligan and co-workers⁴³ injected 1.3 to 16.4 Gm. of hemoglobin in the form of hemolyzed red blood cells into fifteen human subjects. When the plasma level was increased above 135 mg. per 100 c.c., hemoglobin appeared in the urine. When this level was once exceeded, hemoglobin continued to appear in the urine until the level dropped to 30 to 50 mg. per 100 cubic centimeters. They found that albumin was excreted in addition to hemoglobin, even when there was no pre-existing albuminuria, and continued to be excreted for a short time after hemoglobinuria ceased.

Ottenberg and Fox⁷³ injected 3.47 to 8.25 Gm. of hemoglobin as hemolyzed red blood cells into twenty subjects. They found that the renal threshold was quite variable and that five of thirteen subjects with plasma levels from 200 to 288 mg. per 100 c.c. did not have hemoglobinuria. When the plasma hemoglobin level did not exceed the threshold, the curve of disappearance of hemoglobin from the plasma was a straight line.

O'Shaughnessy and associates,⁷² Duesberg,²⁷ and Fairley³²⁻³⁴ also have injected hemoglobin solutions into human subjects. The largest dose injected into any patient was 50 Gm.,⁷² and this amount produced some subjective symptoms but no renal injury. Hemoglobinuria lasted thirty hours. Other investigators also have noted rigors and some pain in the muscles and back from injections of hemoglobin. Duesberg²⁷ showed that the bilirubin concentration of the serum had increased thirty minutes after injection was completed and reached a peak a variable time later depending on the dose of hemoglobin and the patient's condition. Ottenberg and Fox⁷³ confirmed this observation.

The amount of hemoglobin excreted by the kidney after intravenous injection of a solution depends on the dose. Drabkin and associates' statement²⁶ that 9.5 per cent of the injected dose is excreted has been quoted widely, but it has been clearly demonstrated that the percentage varies with the dose injected unless oliguria or anuria are produced and that it may be as great as 33 per cent of the initial dose.^{43, 72, 90} Likewise the duration of hemoglobinuria varies directly with the dose injected but also depends somewhat on the general condition of the patient or animal.

Reid⁷⁷ placed the kidney of a number of dogs in collodion plethysmographs and determined the effect of the injection of distilled water on the renal volume. There was a transient marked decrease in the volume of the kidney after the injection of 0.5 to 1.5 c.c. of water for each kilogram of body weight. The shrinkage lasted one or two minutes. He also injected laked dog blood made isotonic with sodium chloride. Five cubic centimeters of laked dog red blood cells caused the most marked decrease in renal volume, lasting up to twelve minutes. Anesthesia did not abolish the decrease in volume. A denervated kidney responded the same as the normal kidney. Mason and Maun⁶⁷ made direct observations on the frog kidney following the intravenous administration of a solution of pure hemoglobin and concluded that the decrease in volume of the kidney resulted from generalized contraction of the renal arterioles and arteries.

Hesse and Filatov⁴⁸ found that the injection of homologous hemoglobin solutions caused decrease in the renal volume lasting from several to twenty-five minutes, depending on the dose of hemoglobin. Heterologous blood caused a similar shrinkage of the kidney. Initially they found that complete denervation of the kidney prevented the shrinkage of the observed kidney. However, in later experiments by a group of investigators⁸⁹ from the same laboratory, it was clear that decerebration, transection of the cord, cutting the splanchnic nerves, and denervation of the kidney did not prevent the shrinkage; therefore, they concluded that the hemoglobin itself caused spasm of the renal vessels.

Hesse and Filatov⁴⁸ showed that transfusion of compatible blood promptly relieved the spasm of the renal vessels, that is, the volume and pulsations of the kidney returned quickly to normal. On the basis of this evidence they recommend the use of compatible blood transfusion as a treatment of hemolytic transfusion reaction. They believed that all the manifestations of hemolytic transfusion reactions could be explained on the basis of spasm of renal vessels, but later reports by members of the same group, Iljin and Mineev,^{53, 54} conclude that some factor in addition to spasm accounts for renal damage.

Amberson and co-workers² were able to replace completely the blood of cats, dogs, and rabbits with a Ringer-Locke solution containing 12 to 14 Gm. of beef hemoglobin per 100 cubic centimeters. The animals were able to walk around the laboratory but they did not eat or drink and anuria developed. Some lived as long as thirty-six hours.

De Navasquez²⁵ injected hemoglobin solutions into rabbits and determined the iron content of the kidneys. He found that the animals excreting acid urine retained less iron and for a shorter time than those excreting alkaline urine. On the basis of this evidence he concluded that the rabbit was able to excrete hemoglobin better when the urine was acid. The dose of hemoglobin was relatively small, less than 1.0 Gm. per kilogram. Foy and associates⁴⁰ cite evidence that the mammalian kidney is better able to excrete solids when the urine is acid than when the urine is alkaline. This argument, however, does not take into account the matter of solubility of hemoglobin at various pH levels.

Maegraith and Havard⁶⁵ summarized mortality statistics of blackwater fever before the use of alkalies and after their use. In their summary of the series of cases reported by three different authors the mortality rate ranged from 19 to 25 per cent before the use of alkalies. In five different reports, but of a smaller number of patients receiving alkalies, the mortality rate ranged from 20 to 37 per cent. Maegraith and Havard concluded that alkali therapy has not benefited a group though it may have helped individual patients. They also pointed out the fact that patients with oliguria or anuria often continue to have an acid urine in spite of continuing alkali therapy. Anuria developed in some cases where the urine was alkaline immediately before the hemoglobinuria and continued to be alkaline after oliguria commenced. Foy and Kondi²⁹ likewise have observed that patients with alkaline urine develop anuria.

De Navasquez²⁵ acidified the urine of a patient with paroxysmal hemoglobinuria due to cold and then induced an attack by immersion of the arm in ice water. Hemoglobinuria lasted six hours, the highest plasma hemoglobin value was 688 mg. per 100 c.c., and an estimated 13.0 Gm. of hemoglobin were liberated. No renal insufficiency developed, and De Navasquez cites this as evidence that an acid urine is not a factor in renal damage resulting from hemoglobinemia. This, however, represents but a small amount of hemolysis, and it is probably incorrect to draw conclusions one way or the other from De Navasquez' experiment.

There are several considerations which are overlooked in most discussions of hemoglobinemic states, and it would seem that the most important of these is

the actual amount of hemoglobinemia present at the height of the reaction prior to the onset of oliguria or anuria. It is insufficient to determine the level of plasma hemoglobin a day or two after the onset of hemolysis, for it has been amply demonstrated that hemoglobin is rapidly removed from the blood stream in man and in animals.^{33, 34, 43, 72, 73} Foy and Kondi³⁸ determined hemoglobin concentration of their patients with blackwater fever twelve to twenty-four hours after onset. Though they make a statement that the amount of hemolysis seems to be unimportant, their protocols indicate that the patients who died from anuria had the highest levels of plasma hemoglobin. Fairley and Bromfield³¹ found that the highest hemoglobin concentrations occurred in their three fatal cases (3.6, 4.6, and 5.14 per cent of normal hemoglobin concentration in these cases).

The plasma level of hemoglobin was determined in four cases of hemolytic anemia due to sulfonamides by Fox and Ottenberg.³⁷ Twelve to forty-eight hours after the onset of hemolysis the total hemoglobin pigment levels ranged from 0.4 to 1.7 Gm. per 100 cubic centimeters. Two patients died from anemia and renal insufficiency. At autopsy on one patient dying three days after onset, the kidneys showed a large number of hemoglobin casts chiefly in the loops of Henle and distal tubules. Foy and associates⁴¹ studied a patient dying from uremia as a result of an acute hemolytic anemia due to benzyl sulfanilamide. Quantitative determinations of the urine and plasma pigments were carried out, but no mention is made of the hemoglobin level in the plasma until the fifth day after jaundice was noted. At that time there were 291 mg. of methemalbumin (the pigment described by Fairley³⁴) and 90 mg. of oxyhemoglobin per 100 c.c. but no methemoglobin.

The plasma hemoglobin levels in cases of paroxysmal nocturnal hemoglobinuria (Marchiafava-Micheli type) studied by Ham⁴⁰ and Hoffman and Kracke⁵² ranged as high as 279 and 288 mg. hemoglobin per 100 c.c. of plasma. Ham reports one death from renal insufficiency but this patient had an acute pyelonephritis. Altshule and Gilligan³ report a case of acute massive hemoglobinuria with jaundice and anemia. The nonprotein nitrogen rose to 90 mg. per 100 c.c. of blood during the course of the hemoglobinuria but returned to normal afterward. The plasma hemoglobin level was 500 mg. per 100 c.c. twenty-four hours after the onset, but it may well have been higher at some time earlier. Hemoglobinemia continued for eighteen days.

Recently, Shen and co-workers⁸¹ studied eleven patients with hemoglobinuria out of forty with extensive second and third degree burns. Plasma or serum hemoglobin levels ranged from 65 to 215 mg. per 100 c.c. at an unspecified time after the burn. In four out of five patients with hemoglobinuria who lived five days or longer, azotemia of moderate severity occurred in spite of re-establishment of adequate urine flow with fixed low specific gravity of the urine. The kidneys of six patients were studied histologically and were consistent with hemoglobinuria. Olson and Necheles⁷¹ studied burns experimentally and found that renal insufficiency was most likely to occur when the plasma hemoglobin level was highest. They found levels as high as 2,000 mg. per 100 cubic centimeters.

EXPERIMENTAL METHODS

Animal Experiments (Explantation of One Kidney).—Explantation of the kidney has been carried out many times in the past. The first mention of this procedure is made by Allen in 1925.¹ Loesch^{2, 3} explanted kidneys for the purpose of study of experimental hypertension. The renal pedicle was clamped intermittently and hypertension was produced. Biopsies were obtained by subjecting the dog to a surgical procedure. Entz and Huggins²⁹ explanted the kidney extracutaneously and were able to protect it sufficiently to prevent ulceration until a thick leathery capsule developed. Total kidney function as measured by the phenolsulfonphthalein test was unaffected by the procedure. Rhoads⁷⁸ carried out a somewhat more elaborate procedure in that the renal vein was also anchored subcutaneously so that repeated samples of renal vein blood were obtainable. Explantation of one kidney caused no change in the urea clearance. Removal of the other kidney caused no greater fall in urea clearance than if the remaining kidney had been in normal position. Gabriele⁴² showed that the renal blood flow remained the same if the kidney were displaced outward and downward. However, if the renal pedicle were moved upward to form an acute angle with the great vessels, renal blood flow in that kidney decreased. Autopsies in the dogs used in the present experiments revealed an angle of 90 degrees or more with the great vessels and no kinking or stretching were found. Explantation of a kidney does not alter its blood flow appreciably.

Mongrel dogs weighing from 6.25 to 13.6 kilograms were chosen as the experimental animals. Each dog was anesthetized with sodium pentobarbital given intravenously. An oblique incision was made along the right costal margin beginning about 3 cm. from the midline dorsally. The muscle layers immediately caudal to the costal margin were split along the direction of their fibers. The peritoneum was incised and the kidney freed from its peritoneum and perinephric fat by blunt dissection. Care was taken not to dissect around the renal pedicle for the kidney could be mobilized adequately without interfering with the pedicle. The kidney was delivered through the opening in the muscle layers and rotated through an arc of about 75 degrees so that the upper pole was directed dorsally and slightly cephalad. The peritoneum and muscle layers were closed loosely around the pedicle using silk or linen suture material. Finally the skin was sutured using sulfathiazole powder along the incision. No dressings were applied. The skin sutures were removed on the sixth or seventh days. In several dogs there was a minor separation of the skin margins which healed satisfactorily in a short while. One dog suffered a wide separation of the skin margins on the fifth day directly exposing the kidney. The kidney became ulcerated and finally it was necessary to sacrifice the dog without using it for an experiment. This was the only failure out of eleven dogs operated upon. The postoperative tissue reaction usually subsided in two or three weeks. The kidney was mobile to a certain extent but often the skin was attached to it.

Biopsy Technique.—When the reaction to operation had completely subsided the area over the explanted kidney was shaved and prepared with Novak's antiseptic. One per cent procaine hydrochloride solution was used as a local anesthetic. A Silverman needle* was used to obtain biopsies of the kidney. Tripoli and Faders⁴ and Hoffbauer⁵¹ have used this instrument for biopsy of the liver. The author is indebted to Dr. Hoffbauer for helpful suggestions regarding the use of the needle. The poles of the kidney were used for biopsy sites for the most part. The needle was directed in such a way as to avoid the hilus region. The core of kidney tissue removed was placed in 10 per cent formalin in physiologic saline solution. As soon as the needle was removed the kidney was compressed between two fingers for a period of three to five minutes; it was possible to prevent hematoma formation at the site of biopsy by this compression. About 80 per cent of attempted biopsies were successful in obtaining satisfactory tissue for sectioning. In earlier experiments biopsies were obtained prior to any injection, but in later experiments biopsies were obtained only after injection. Sixty satisfactory biopsies were made and as many as ten from a single kidney were obtained.

*Vlm No. 14 made by the MacGregor Instrument Co., Needham, Mass.

The specimens were mounted in paraffin and stained with hematoxylin eosin stain. Some of the autopsy specimens were also stained for free iron using potassium ferrieyanide and hydrochloric acid.

Biopsies were not entirely innocuous in every instance. One animal (Dog 6) died as a result of abscesses in the lower pole of the kidney at the site of a biopsy, and another (Dog 11) had a small abscess at one pole of the kidney. Dog 9 had a hematoma in the lower pole of the kidney as a result of the operation or of the control biopsy, most likely the former. At autopsy most of the kidneys were pitted at the site of some biopsy but only very small areas were involved.

Preparation of Hemoglobin and Hemolyzed Red Blood Cell Solutions.—Blood was obtained from dogs which were to be sacrificed for various reasons but were not ill. The blood was collected in sterile containers with sodium citrate as an anticoagulant. The red blood cells were allowed to sediment for four or five days, the plasma was removed by aspiration, and the remaining cells were washed three times with sterile sodium chloride solution (The cells were not washed for Experiments 2 through 4). The washed cells then were stored in a deep freezing unit (the cells were laked immediately for experiment 7b). The night before contemplated use two volumes of sterile distilled water were added to the cells. After several hours an amount of sterile hypertonic sodium chloride solution was added to make the solution isotonic. The laked cells were then centrifuged for one hour and the supernatant solution was removed by aspiration. The process of laking the cells and making the solution was carried out in the twelve-hour period before the use of the solution which was stored in a refrigerator all the time except during centrifugation. Spectroscopic examination of each solution was carried out immediately before its administration, and oxyhemoglobin alone was observed in all of the solutions prepared by laking the blood cells as previously described. Cultures were obtained on four occasions and no bacterial contamination was found at any time. Sterile precautions were taken in making all of the solutions. The hemolyzed erythrocyte solutions were used in Dogs 2 to 9.

The method of Bing¹¹ was used to prepare crystalline dog hemoglobin for use in three experiments for Dogs 10 and 11. The blood was collected and treated as described to obtain red blood cells. One-fifth volume of toluene was added to each bottle of washed cells; the bottles were vigorously shaken for five minutes and then allowed to stay in the refrigerator for twenty-four hours. The mixture was then centrifuged and the toluene layer and a creamy layer, presumably the stroma and lipid layer, were decanted. The crystalline deposit was washed three times with cold sterile distilled water and centrifuged each time. Finally the crystalline deposit was dissolved in sterile saline solution. The crystals were found to be relatively insoluble unless some sterile sodium bicarbonate solution was added. (The amounts will be specified in individual experiments.) Before injection in each instance the solution was centrifuged and the clear supernatant solution used for intravenous injection. Cultures of this solution were found to be sterile in each of two instances in which cultures were obtained. As will be seen, much larger amounts of hemoglobin were used than were used by Bing. Methemoglobin was not detected by spectroscopic examination in the first two solutions used but was detected in the solution used in Experiment 10b and in one solution which was discarded.

Injection Experiments.—Each dog was given either ammonium chloride or sodium bicarbonate by mouth or stomach tube before the injection. At first 10 Gm. of either sub-bicarbonate quite well and this method was entirely satisfactory in producing alkaline urine each time it was used. The ammonium chloride was not tolerated well. In most instances it caused vomiting and several dogs exhibited convulsive disturbances immediately after intubation. On these occasions experiments had to be postponed and the hemoglobin solutions discarded. Enteric-coated ammonium chloride tablets given orally in doses of 3 Gm. at approximately intervals of eighteen hours, twelve hours, and one hour before the experiment proved to be very satisfactory in producing an acid urine and were well tolerated. It is difficult to understand how as much as 120 Gm. of ammonium chloride could have been given to dogs in forty-eight hours as described by Bing¹¹ without causing severe disturbances.

The dogs were anesthetized with sodium pentobarbital given intravenously and catheterized leaving the catheter in place for eight to ten hours after completion of the injection of hemoglobin or hemolyzed blood solution. No. 8 French ureteral catheters were used for male dogs. Blood was obtained for hematocrit determination after which the solution was injected at a rate of about 20 c.c. per minute into a forepaw vein. Subsequently, blood specimens for plasma examination and hematocrit were obtained by venepuncture or femoral artery puncture immediately after completion of injection and at intervals during the first eight hours. Isotonic sodium citrate was used as an anticoagulant in the first four experiments, but a correction for the volume of citrate solution is necessary since an appreciable dilution occurs when one volume of solution to nine volumes of blood are used. For the rest of the experiments one drop of 25 per cent sodium citrate solution per 5 c.c. of blood was used and no correction for dilution was made. Artificial hemolysis is not induced by the 25 per cent sodium citrate when the blood is otherwise handled with care.

Urine was collected at variable intervals depending on the rate of urine flow. An attempt was made to collect separately urine of grossly comparable concentration. After removal of the catheter all the urine was collected by the use of metabolism cages. Freshly voided specimens were collected when possible during the first few days after the injection.

Chemical Procedures and Other Methods.—The concentration of hemoglobin in the solution, the plasma, and the urine was determined by the pyridine hemochromogen method described previously.³⁵ The urine hemoglobin concentrations were determined directly, that is, without extraction with ether, for the concentrations were great. It was found that no error resulted by using the method described for plasma. Both urine and plasma had such great concentrations of hemoglobin that it was necessary to use 0.02 to 0.10 c.c. samples initially and from 0.1 to 0.5 c.c. later. It is necessary to use the reagent grade of pyridine in order to get uniform results. The method is as follows: The citrated blood is centrifuged as soon as it is obtained and the plasma is withdrawn. Plasma samples (0.02 to 0.05 c.c. or more up to 0.5 c.c.) are placed in Evelyn colorimeter tubes. The plasma is diluted with dilute ammonium hydroxide to 7.5 c.c. and finally to 10 c.c. with 0.5 c.c. of pyridine and 2.0 c.c. of freshly prepared 0.2 per cent sodium hydrosulfite. A duplicate tube for center setting determinations is set up in the same manner but with 1.0 c.c. less ammonium hydroxide, thus allowing for 1.0 c.c. of 3 per cent hydrogen peroxide. Readings are obtained in five minutes. The following formula is used:

$$\text{Concentration} = \frac{1000 \times L}{K \times V} \text{ mg. hemoglobin per 100 c.c. plasma}$$

L - (2 - log G) = "L" value

G - galvanometer readings

V = c.c. of plasma used

K = 1.843.

Hematocrit determinations were made using dry mixed ammonium and potassium oxalate as anticoagulant and the Wintrobe hematocrit tube. Unfortunately, several control specimens clotted so that some of the experiments had to be excluded from certain calculations involving hemodilution, etc. Blood specimens were usually obtained at twenty-four hour intervals for the duration of hemoglobinemia and at variable intervals for the determination of the blood urea nitrogen, depending on the circumstances of each experiment. The blood urea nitrogen was determined by the direct nesslerization of a Folin-Wu filtrate of blood incubated with urease.³⁵ The method has been adapted for use with the Evelyn colorimeter.

Microscopic examination of urine sediment was carried out at intervals as seen in the tables of each experiment. Only fresh urine specimens were examined.

Spectroscopic examinations were carried out using a Zeiss hand spectroscope. Methemoglobin concentrations in Experiment 10b were carried out by the method of Evelyn and Malloy.³⁰

The pH of the urine was determined by the use of a Coleman No. 3 electrometer. When the reaction is recorded as alkaline or acid, alkacid ribbon* was used. The pH was determined in two hours or less after collection directly from the dog.

*Fisher Scientific Co., Pittsburgh, Pa.

EXPERIMENTAL OBSERVATIONS

Nineteen experiments on ten dogs were done. Serial biopsies were obtained in eleven experiments and were satisfactory for pathologic examination. The earliest biopsies were obtained four to eight hours after injection of hemoglobin solutions in Experiments 3, 4, 5a, 6, 7a, 8, 9, and 10b and twenty-four hours afterward in Experiments 7b, 10a, and 11.

Data regarding the volume, quantity of hemoglobin, plasma hemoglobin levels, hemodilution as measured by hematocrit changes, duration and extent of hemoglobinuria, pH of the urine during the first twenty-four hours, blood urea nitrogen levels, presence of casts are recorded in Tables I and II. The data regarding the first four experiments are not included because of the relatively small quantities of hemoglobin injected, but some of these experiments are represented on the graphs listed as Experiment 2a to 2d. Two dogs died shortly after the injection was completed (Experiments 2g and 5b).

Dogs 5a, 6, 7a, 7b, and 10a recovered promptly from the effect of the infusions and anesthesia. Dogs 5a, 6, and 7a had acid urine and Dogs 7b and 10a had alkaline urine. Dog 6 developed an infection (proved to be renal abscesses at autopsy) and became progressively more ill after the fourth day. None of the above dogs developed renal insufficiency. Dogs in Experiments 3, 4, 8, 9, 10b, and 11 developed renal insufficiency at least temporarily or died from uremia. Dogs 3, 4, 8, and 10b had alkaline urine and Dogs 9 and 11 had acid urine. Dog 3 was seriously ill for about three weeks; then it recovered partially but contracted a respiratory infection and died from pneumonia on the forty-sixth day. Dog 8 was ill from the time of injection and contracted a respiratory infection on the fourth day but responded to sulfadiazine therapy and recovered. Dog 4 was ill for three or four days but recovered completely. Dogs 9 and 11 became progressively more ill and had twitchings and convulsions terminally, vomited frequently, and died from uremia. Dog 10b died approximately thirty-six hours after injection; the immediate cause of death was not determined but there was extensive renal damage at autopsy.

One animal (Dog 5b) died three hours after the injection, either from shock or from cardiac irregularity which was noted just before death. There was a moderate amount of free peritoneal fluid which contained 2.5 Gm. of hemoglobin per 100 cubic centimeters. In the other experiments the spleen and liver often were engorged at the time of injection and the veins were greatly distended. In Experiment 2g the dog died about eight hours after completion of the injection. The spleen was large and the peritoneal cavity contained hemoglobin-stained fluid. All the organs had hemorrhagic areas throughout their substance. The lumen of the intestines contained a considerable quantity of blood.

Unfortunately blood pressure determinations were not obtained. From observation of the pulse volume there probably was some lowering of the blood pressure in the first eight-hour period. It is significant that at no time did anuria occur; in other words, the blood pressure did not decrease enough to cause complete failure of excretion of urine.

TABLE I. SUMMARY OF DATA REGARDING DOSE OF HEMOGLOBIN, PLASMA LEVELS OF HEMOGLOBIN, HEMODILUTION, AND HEMOGLOBIN EXCRETION

DOG	WEIGHT (KG.)	HEMOGLOBIN SOLUTION			PLASMA HEMOGLOBIN (GM./100 C.C.) IN HOURS AFTER INJECTION OF HEMOGLOBIN SOLUTION								HEMODILUTION† (%)	EXCRETION (%)	HOURS OF HEMOGLOBINURIA	REACTION OF URINE

*The time in hours is indicated by the number in parentheses.

†Hemodilution is an expression of the ratio of initial hematocrit to the lowest hematocrit after injection.

‡Solutions of crystalline hemoglobin were used in these three experiments.

EXPERIMENTAL OBSERVATIONS

Nineteen experiments on ten dogs were done. Serial biopsies were obtained in eleven experiments and were satisfactory for pathologic examination. The earliest biopsies were obtained four to eight hours after injection of hemoglobin solutions in Experiments 3, 4, 5a, 6, 7a, 8, 9, and 10b and twenty-four hours afterward in Experiments 7b, 10a, and 11.

Data regarding the volume, quantity of hemoglobin, plasma hemoglobin levels, hemodilution as measured by hematocrit changes, duration and extent of hemoglobinuria, pH of the urine during the first twenty-four hours, blood urea nitrogen levels, presence of casts are recorded in Tables I and II. The data regarding the first four experiments are not included because of the relatively small quantities of hemoglobin injected, but some of these experiments are represented on the graphs listed as Experiment 2a to 2d. Two dogs died shortly after the injection was completed (Experiments 2g and 5b).

Dogs 5a, 6, 7a, 7b, and 10a recovered promptly from the effect of the infusions and anesthesia. Dogs 5a, 6, and 7a had acid urine and Dogs 7b and 10a had alkaline urine. Dog 6 developed an infection (proved to be renal abscesses at autopsy) and became progressively more ill after the fourth day. None of the above dogs developed renal insufficiency. Dogs in Experiments 3, 4, 8, 9, 10b, and 11 developed renal insufficiency at least temporarily or died from uremia. Dogs 3, 4, 8, and 10b had alkaline urine and Dogs 9 and 11 had acid urine. Dog 3 was seriously ill for about three weeks; then it recovered partially but contracted a respiratory infection and died from pneumonia on the forty-sixth day. Dog 8 was ill from the time of injection and contracted a respiratory infection on the fourth day but responded to sulfadiazine therapy and recovered. Dog 4 was ill for three or four days but recovered completely. Dogs 9 and 11 became progressively more ill and had twitchings and convulsions terminally, vomited frequently, and died from uremia. Dog 10b died approximately thirty-six hours after injection; the immediate cause of death was not determined but there was extensive renal damage at autopsy.

One animal (Dog 5b) died three hours after the injection, either from shock or from cardiac irregularity which was noted just before death. There was a moderate amount of free peritoneal fluid which contained 2.5 Gm. of hemoglobin per 100 cubic centimeters. In the other experiments the spleen and liver often were engorged at the time of injection and the veins were greatly distended. In Experiment 2g the dog died about eight hours after completion of the injection. The spleen was large and the peritoneal cavity contained hemoglobin-stained fluid. All the organs had hemorrhagic areas throughout their substance. The lumen of the intestines contained a considerable quantity of blood.

Unfortunately blood pressure determinations were not obtained. From observation of the pulse volume there probably was some lowering of the blood pressure in the first eight-hour period. It is significant that at no time did anuria occur; in other words, the blood pressure did not decrease enough to cause complete failure of excretion of urine.

TABLE I. SUMMARY OF DATA REGARDING DOSE OF HEMOGLOBIN, PLASMA LEVELS OF HEMOGLOBIN, HEMODILUTION, AND HEMOGLOBIN EXCRETION

*The time in days is indicated in the parentheses.

†The volumes may not be accurate for the dogs with renal insufficiency after the third or fourth day, since these dogs vomited and the vomitus would be collected just as voided urine would be.

‡Solutions of crystalline hemoglobin were used in these experiments.

An attempt was made to determine the size of the kidney by palpation during the immediate postinjection period. In no instance did the kidney seem to shrink in size, but in several dogs it seemed to enlarge slightly. For several hours following injection the consistency was uniformly firmer than before. External measurements by means of a ruler confirmed the impression that shrinkage did not occur. Of course, there may have been some change in volume which could have been determined only by plethysmography.

From the data in Table II it is evident that methemoglobin appeared in the urine much earlier when the urine was acid than when it was alkaline. In all except Experiment 10b the hemoglobin solution contained no methemoglobin or less than is detectable by spectroscopic examination. The solution used in 10b contained 13 per cent methemoglobin and the rest was oxyhemoglobin.

The results of the renal biopsies can be summarized for Experiments 5a and 5b, 6, 7a and 7b and 10a by stating that little or no renal damage could be detected at any time after injection. Rarely casts were found in some of the tubules during the period of hemoglobinuria and were fairly numerous in Experiment 7a. (Sections are normal otherwise so they will not be illustrated.) The convoluted tubule cells contained many granules of pigment which had the staining qualities of hemosiderin. A few of these granules were found in the kidney as long as 112 days after injection (Dog 4). Hemosiderin granules were numerous in the reticulo-endothelial cells of the spleen and liver, too. The explanted kidney of Dog 6 was partially destroyed by multiple abscesses, but the rest of the kidney and the normally placed kidney were entirely normal at autopsy. The same fundamental structural changes were present in the normally placed kidney as in the explanted one at autopsy in every dog, except when an abscess (Dog 6 and 11) or hematoma (Dog 9) were found in the explanted kidney.

Casts appeared in the urine in abundance in practically every experiment. The casts were brown and granular in appearance. Although quantitative determinations were not made, it was apparent that the number of casts was greater in some experiments when the urine was acid than in any when it was alkaline. The casts were not identified chemically but very likely were derived from hemoglobin because of their brown-red color and their occurrence immediately after hemoglobinuria started. The casts in the tubules of the kidney did not stain with ferrieyanide so they did not contain any free iron. Many of the casts in the tubules had a crystalline structure. The casts stained uniformly with the eosin stain and had a color similar to red blood cells stained with eosin.

The pathologic findings in dogs with renal damage were more interesting. The urine was alkaline during the first twenty-four hours in Experiments 3, 4, 8, and 10b and acid in Experiments 9 and 11. An attempt will be made to illustrate early damage, its progress, and finally partial or complete healing. Space does not permit inclusion of description of all of the sections obtained; therefore, only the most characteristic findings will be described.

Four hours after the injection in Dog 3 there was slight vacuolization of the epithelial cells in the proximal and distal convoluted tubules and there were

Fig. 1.

Fig. 2.

Fig. 1.—Kidney, Dog 3; alkaline urine; biopsy obtained one day after injection of hemoglobin solution. Numerous casts are evident and there are early degenerative changes in the tubular epithelium ($\times 150$).

Fig. 2.—Kidney, Dog 3, biopsy obtained five days after injection of hemoglobin solution. There are very extensive degenerative changes in the tubule cells. Other portions of the same section have many hemoglobin casts in the tubules ($\times 300$).

Fig. 3.

Fig. 4.

Fig. 3.—Kidney, Dog 3; biopsy obtained seventeen days after injection of hemoglobin solution. The epithelium of the convoluted tubules shows many evidences of healing as well as persisting degenerative changes in other areas (X150).

Fig. 4.—Kidney, Dog 3; autopsy forty-six days after injection of hemoglobin solution. There are narrow wedges of normal cortex interposed between areas of tubular atrophy. The convoluted tubule cells in the atrophic areas have many hemosiderin granules (when stained with a ferricyanide stain). The lumina of the atrophic tubules are narrow but patent. The photomicrograph depicts an area of healed cortex adjacent to one atrophy with large hemoglobin casts (X150).

many hemoglobin casts in the loops of Henle and of the distal convoluted tubules. The cytoplasm of the cells of the proximal convoluted tubules had red staining globules. Twenty-four hours after the injection the lumina of the majority of loops of Henle and distal convoluted tubules were full of hemoglobin casts (Fig. 1). There was swelling of the cells of some proximal convoluted tubules and the nuclei were pyknotic. At forty-eight hours the tubular epithelium showed further degeneration. At five days extreme vacuolization of the cells and some disorganization of the tubules in both the cortex and corticomedullary portion had appeared (Fig. 2). The number of casts in the corticomedullary portion (not shown in the photomicrograph) was as numerous as on the first day. At ten days there was evidence of beginning regeneration of tubule cells. At seventeen days most of the casts were in the corticomedullary portion. In the cortical portion as shown in Fig. 3, some of the tubules were lined by flat or low cuboidal cells and apparently were undergoing atrophy, but others were regenerating and had nearly normal appearance.

Fig. 5.—Kidney, Dog 8; alkaline urine; autopsy thirty-five days after injection of hemoglobin solution. Most of the cortex appears to be normal, but there are wedge-shaped areas of atrophy in which the tubules are shrunken or dilated and there are hemoglobin casts in the medullary tubules ($\times 205$).

At autopsy on the forty-sixth day the surfaces of the kidneys were finely pitted. On section it was evident that the pits were represented by radial streaks of atrophy. In an unstained section the medulla had brownish-red radial streaking. There were narrow wedges of normal cortex interspersed with areas of atrophy and casts. The lumina of the atrophic tubules were narrow but patent. Fig. 4 depicted an area of healed cortex adjacent to one of atrophy with large hemoglobin casts in the lumina of the atrophic tubules (forty-six days).

Fig. 6.

Fig. 7.

Fig. 6.—Kidney, Dog 4; alkaline urine; biopsy obtained five hours after injection of hemoglobin solution. A large number of hemoglobin casts are present in the loops of Henle and in the distal convoluted tubules. Some casts have a crystalline appearance, but others appear amorphous ($\times 150$).

Fig. 7.—Kidney, Dog 10; alkaline urine; biopsy obtained eight hours after injection of solution of hemoglobin crystals. There are numerous casts throughout the cortex and early degenerative changes ($\times 150$).

The findings in Dog 8 were similar qualitatively. The number of casts and the degenerative changes were less marked and the kidneys at autopsy showed much less permanent damage and casts than in Dog 3. Some of the atrophic tubules were dilated (Fig. 5). The renal function had returned practically to normal as evidenced by concentrating ability of the kidney. It is entirely possible that further repair of the anatomic damage would have occurred if the dog had been permitted to live.

The changes in Dog 4 were just as severe in the early stages as in Dog 8, but the progress toward complete healing was rapid after the eleventh day. Some pigment casts and atrophic tubules were evident in biopsies obtained at fifty-one and eighty-three days. At autopsy the kidneys were entirely normal with the exception of rare pigment casts and atrophic tubules. Fig. 6 from a biopsy obtained five hours after the hemoglobin injection revealed the very early appearance of casts in the tubules in spite of the continuous alkalinity of the urine. Experiments 4 and 8 illustrate the power of the kidney to regenerate after severe tubular damage.

In Experiment 10b the dog was given a solution made from 48.4 Gm. of crystalline hemoglobin. Thirteen per cent of the hemoglobin in this solution was methemoglobin. The pulse rate diminished to a low of 44 beats per minute six hours after the injection, and the pulse was weak. Twenty-four hours afterward the dog was listless and weak, but the pulse rate was 100 per minute and the pulse was strong. The dog was found dead forty-four hours after injection. Autopsy was not performed until fifty-two hours, or at least twelve hours after death. Unfortunately, considerable autolysis had occurred by this time. A biopsy (Fig. 7) obtained at eight hours revealed very many casts throughout the cortex. At autopsy the casts were more numerous. The tubule cells were badly degenerated (at least some of this represents post-mortem autolysis).

The results of Experiments 9 and 11 are so much alike that a description of the findings in Experiment 11 will suffice. Part of the explanted kidney in Dog 9 was replaced by an old hematoma. The hematoma probably was the result of trauma at the time of explantation, for there was troublesome bleeding from an artery over the lower pole. The hematoma may have been due to the initial biopsy.

In Experiment 9 hemolyzed red cells were used, but in Experiment 11 a solution made from crystalline hemoglobin was used. Dog 9 died on the seventh day and Dog 11 was killed on the tenth day, for it was obviously moribund. Each dog vomited after the third or fourth day but not before.

In Experiment 11, at twenty-four hours, there were many casts throughout the cortex and corticomedullary portion occluding the lumina of most of the loops of Henle and the distal segment. There were degenerative changes in the tubules not containing casts (Fig. 8). At three days degenerative changes were marked with desquamation of tubular epithelium, poor staining, and vacuolization of the cytoplasm and pyknosis of nuclei. Casts were very numerous. At six days the cells of the convoluted tubules were severely injured with more marked changes than noted at three days. At autopsy (ten days, Fig. 9) there

Fig. 8.

Fig. 9.

Fig. 8—Kidney, Dog 11; acid urine; biopsy obtained one day after injection of a solution of hemoglobin crystals. The number of hemoglobin casts is the greatest of any of the experiments. There are degenerative changes in the tubules in the cortex ($\times 265$).

Fig. 9—Kidney, Dog 11; autopsy ten days after injection of solution of hemoglobin crystals. The number of casts remains as large in the medulla and corticomedullary portions but is less in the cortex. Cortical tubules show degenerative changes progressing to atrophy of some and dilatation of others ($\times 265$).

were many casts in the corticomedullary portion. In the cortex there was evidence of atrophy of some tubules, dilatation of others, and continued degeneration as previously noted. There was evidence of healing of some of the degenerated tubule cells. The explanted kidney had a small abscess at the lower pole, but the rest of the pathologic findings were identical in the two kidneys.

Microscopic examination of the urine was carried out at frequent intervals as indicated in Tables I and II. Casts described, unless otherwise specified, were large, dark brown, and granular. Some casts had square ends but most of them had a shape similar to any tubular casts. In Dog 11 casts appeared in the very first urine obtained after injection of hemoglobin but also in the urine of most dogs very soon after hemoglobinuria started. Because of catheterization the significance of hematuria is questionable.

In Dogs 3, 4, 8, 9, 10a, and 11 retention of urea nitrogen, excretion of urine of low fixed specific gravity, albuminuria, and in three dogs, death from uremia are interpreted as evidences of renal insufficiency. There probably was an increased rate of protein metabolism in these dogs. When one subtracts the amount excreted, the dose of the administered hemoglobin did not constitute more than a large protein meal which any dog can eat in one day. It is doubtful that vomiting and dehydration had any significant role in these cases until development of frank renal insufficiency and uremia. Dogs 9 and 11 did not begin to vomit until uremia was well established. Dog 4 developed only transient renal insufficiency and probably could be classed with the other group, but it is classed in the group with renal insufficiency because of the histologic manifestation of moderate characteristic renal damage. No dogs developed anuria, but the dogs with renal damage continued to excrete rather large volumes of low specific gravity urine. One determination of the ratio of the urine urea nitrogen to blood urea nitrogen was made. It was found to be 455/155 on the fifth day in Experiment 11. This is further evidence of failure to concentrate urinary solids. Other workers^{16, 31, 81} have observed the development of uremia in spite of excretion of normal or even large volumes of urine.

Graph I depicts the disappearance of hemoglobin from the plasma as evidenced by the plasma hemoglobin levels during the first twenty-four hours. It may be noted that there is a rather sharp decline in levels during the first four hours, but after that there is a more gradual and uniform decline. Hemoglobinemia continued for forty-eight hours or longer in all of the cases except in the experiments on Dog 2. (See Tables I and II for these details.) The duration of hemoglobinemia is directly related to the dose of hemoglobin administered.

There is a relationship between the initial plasma hemoglobin level and the dose of hemoglobin, but as illustrated in Graph II there are individual variations which cannot be readily explained on the basis of differences in hemodilution. One factor of importance is the concentration of the administered solution. In every experiment (except Experiment 11) in which the initial plasma hemoglobin level was above 3.5 Gm. per 100 c.c., the concentration of the solution administered was greater than 7.0 Gm. per 100 cubic centimeters. Dog 10 is a good example of this effect, for with comparable doses of hemoglobin the initial

Graph I. Plasma hemoglobin concentrations during the first twenty-four hours.

plasma level was 3.38 when the concentration of the solution was 4.10 Gm. per 100 c.c. and 5.63 Gm. per 100 c.c. when the concentration of the solution was 10.74 Gm. per 100 cubic centimeters. Of course, the factor of concentration is affected by the time necessary for administration and also by the total dose administered, so the effect of concentration probably is a combination of factors. Nevertheless, it is desirable to administer as concentrated a solution as possible in order to cause renal damage.

Graph 11. Initial plasma hemoglobin concentration related to dose of hemoglobin.

Graph 11.

There are many factors affecting the disappearance of hemoglobin from the circulation. Graph III illustrates the constant occurrence of hemodilution in the experiments. The ratio of control hematocrit to hematocrit at the time is used, for it approximates the true extent of hemodilution. It may be noted that Dog 5 developed very definite hemoconcentration at three hours and died twenty minutes later. Dog 11 also developed a minor degree of hemoconcentration at eight hours, but the rest of the dogs either returned to normal or maintained some hemodilution at eight hours. When the blood for the control hematocrit

clotted, the experiment is not represented in the graph. The statement has been made that shock occurs in acute hemolytic conditions because of the sudden disappearance of a large volume of red blood cells,³⁷ but it must be remembered that the hemoglobin remains in solution for a time. Because of the osmotic effect of hemoglobin the volume of blood probably is maintained at its original level initially and only gradually decreases. Furthermore, the osmotic effect of hemoglobin probably limits the level of hemoglobin which can be attained by injection of solutions.

Graph III.

Splenic enlargement, which was evident on palpating the abdomen of all dogs immediately after completion of the injections, is also a manifestation of hemodilution. Another factor which cannot be evaluated accurately in the previously mentioned experiments is the occurrence of ascites with hemoglobin in the ascitic fluid. Ascites was present in Dogs 2 and 5 which died during the first eight hours of the experiments. In Experiment 5b it was possible to determine the hemoglobin level in the fluid a short time after the last plasma hemoglobin determination. The ascitic fluid level was only slightly lower than the plasma level. It is entirely possible that ascites was present during the early part of each experiment.

In order to eliminate or to compensate for the two major factors influencing the level of hemoglobin, namely, hemodilution and excretion of hemoglobin by the kidney, the plasma hemoglobin levels were multiplied by the ratio of control hematocrit to the hematocrit at the time and by the ratio of the initial dose of hemoglobin to the difference between the total dose and the amount excreted up

to that time. Graph IV depicts the approximately corrected hemoglobin levels. It is seen that there is a more uniform disappearance rate illustrated by this graph than by plotting the hemoglobin levels directly as in Graph I.

The body of the dog is removing hemoglobin from the circulation at a relatively constant rate. The correction for hemodilution is justified, for it gives the plasma hemoglobin level which would theoretically occur if all the hemoglobin were contained in the original blood volume. The correction for renal excretion is also justified if one is considering the ability of the organism to remove hemoglobin from the circulation, exclusive of the kidneys. The results in Experiments 4 and 10b cannot be explained readily..

Graph IV. Plasma hemoglobin concentrations corrected for hemodilution and renal excretion.
 (Concentration $\times \frac{\text{hematocrit (control)}}{\text{hematocrit (at time)}} \times \frac{\text{total dose}}{\text{dose} - \text{excr.}}$)

Graph IV.

The amount of hemoglobin excreted is dependent on several factors. Graph V shows the scatter of per cent of hemoglobin excreted in relation to dose administered. It can be seen that there is an even distribution of dogs with acid urine and those with alkaline urine when large doses were administered. It may be seen also that the lowest and the highest percentage excretion were found in

dogs with alkaline urine when the larger doses were used. As might be expected, the dogs developing renal insufficiency excreted somewhat lower percentages than the other dogs. These findings do not agree with those of De Navasquez²⁵ who used much smaller doses in rabbits, but it is believed that these results are more significant since the doses used were sufficient to cause definite renal injury in about half of the dogs. The percentage of total dose excreted is in agreement with observations of other investigators.^{43, 72, 73}

Graph VI depicts the relationship of hemoglobin excretion in the first eight hours to total excretion and to urine volume. The amount of excretion in the first eight hours is roughly related to the development of renal insufficiency, but there is enough overlapping of values that no generalization can be made. Notice the closely comparable curves of volume of urine in the two groups.

The plasma hemoglobin level of dogs given large doses of hemoglobin does not appear to be correlated very closely with the maximum urine concentration. It is noteworthy that in Experiment 2a the maximum urine concentration was ten times that of the plasma. The maximum concentrations in the urine occurred some time after completion of the injection and usually in the period from six to eight hours afterward. This may be related to available water for urine dilution.

Graph VI. Excretion of hemoglobin in per cent of initial dose and volume of urine in first eight hour period.

Graph VI.

DISCUSSION

The results obtained by explanting one kidney of a dog and using a Silverman biopsy needle have been satisfactory. It has been possible to obtain specimens for histologic examination of the kidney at as frequent intervals as considered useful during the course of the experiments previously described. That representative samples of the kidney are obtained has been demonstrated by comparing the biopsy with autopsy specimens of the same animal a short time later. Up to now the progress of a lesion of the kidney produced by hemoglobin or other chemical agents has been studied by sacrificing animals at intervals after introducing the noxious agent or by examining the animals as they died of renal insufficiency. The method of obtaining serial biopsies should be of considerable use in the further study of induced hemoglobinuria, renal damage by chemical poisons, and experimental renal hypertension.

There are some disadvantages to the method of needle biopsy. In two animals (Dogs 6 and 11) the explanted kidney had abscesses at one pole. Since none of the rest of the kidney or of the other kidney had evidence of suppura-

tion, it is reasonable to ascribe the infection to an introduction of bacteria by the needle. More care in scrubbing and preparing the skin probably would have eliminated one of the abscesses. In the other case the novocain solution was contaminated and probably caused the infection. Small areas of infarction and later scarring of the parenchyma occurred after some of the biopsies. Hematuria resulted in some instances, and it was usually possible to identify microscopically some epithelium of the pelvis in the biopsy when hematuria had occurred. There were no serious sequelae from the hematuria. The procedure was carried out occasionally without success in obtaining an adequate specimen. It can be done by a single individual, but help to compress the kidney afterward, to hold the dog, and to steady the needle makes the procedure easier and more certain of success.

It is suggested that a record of sites of biopsy be kept on a diagram of the kidney so that the same area is not used more than once. This was not done in any of the previously mentioned experiments, but some of the unsatisfactory biopsies could have been averted and less scarring of the kidney probably would have resulted.

In all dogs which developed renal insufficiency a number of casts persisted after cessation of hemoglobinuria. The most severe renal insufficiency occurred in the dogs with most marked accumulation of casts in the tubules (Experiments 9, 10b, and 11). Dog 3 developed severe renal insufficiency but had begun to recover some renal function when it died from pneumonia. The number of casts was almost as great as in the previously mentioned three instances. Dog 8 developed renal insufficiency lasting a shorter time than that of Dog 3. Dog 4 developed the mildest renal insufficiency and evidence of renal damage of the group. Again, the degree of insufficiency was correlated with the accumulation of casts in the cortex and medulla of the kidneys. The amount of tubular epithelial injury was directly correlated with the number of casts. In other words, hemoglobin casts and tubular epithelial injury are factors of equal significance in the production of renal insufficiency.

The specific gravity of urine in patients with blackwater fever is said to be variable and of no significance, but an examination of the protocols of patients dying from uremia^{6, 95} reveals a fixed specific gravity of the urine even in the face of a severe oliguria. In burned patients with uremia following hemoglobinuria⁶¹ normal or large volumes of urine with fixed low specific gravity were excreted. Ross⁷⁹ reported a group of patients with blackwater fever who never developed anuria and yet had renal insufficiency. Fairley and Bromfield³¹ report a patient with blackwater fever who had polyuria from the start, developed uremia and acidosis, but eventually recovered.

Patients who have developed renal insufficiency as the result of any acute hemolytic episode may recover completely without any signs of renal damage on testing years later.^{15, 45, 68} The recovery of animals after developing severe renal insufficiency has also occurred. In the present study it has been possible to follow the course of degeneration and subsequent healing or partial healing in Dogs 3, 4, and 8. Figs. 2 to 5 reveal the gradual process of healing from a

stage of severe injury (Fig. 2) to healing of some of the tubules and atrophy of others (Figs. 4 and 5). Less marked renal damage developed in Dog 4 and a longer period of observation was possible so that it had practically normal appearing kidneys 112 days after injection of hemoglobin. In some sections of the kidney in this dog an occasional atrophic tubule and rarely a cast could be seen but, for the most part, the kidney was normal. The appearance of the sections in Dog 8 is intermediate between those of Dogs 3 and 4. In Dog 11 which lived ten days after injection, there was evidence of beginning repair of the tubules of the cortex.

The histologic changes in the various experiments correspond with those reported by other investigators^{6, 9, 50, 55} and to the photomicrographs published by DeGowin and co-workers.²⁴ It is noteworthy, though, that dogs which had distinctly alkaline urine developed renal insufficiency of all degrees of severity and that the histologic appearance cannot be distinguished from the dogs with acid urine which developed renal injury. This is at variance with the findings of DeGowin and co-workers. Furthermore, they found only minor degenerative changes in the tubular epithelium of most of their dogs dying from renal insufficiency. Their photomicrograph showing regeneration corresponds to findings in some of the experiments mentioned in the article. Some necrosis and desquamation of tubular epithelium was noted in the kidneys of a few of their dogs.

The histologic appearance of the kidneys of the previously described dogs developing renal insufficiency are very similar to the pathologic findings in clinical cases.^{7, 21, 24, 45} Most of the reported cases of death from renal insufficiency occur on an average of seven to ten days after the initiating hemolytic accident, so that the findings correspond to those at the height of degenerative changes in the tubular epithelium and also at a time when the number of casts in the cortex seems to be diminishing in the dog experiments. When death occurs as early as twenty-four hours after the hemolytic episode, the tubule cells already show some degenerative changes. The appearance of hemoglobin casts in the renal tubule is a constant finding in the cases of hemoglobinuria with anuria in human beings and it is therefore pathognomonic of hemoglobinuria.

In reports of clinical cases the number of casts noted was often small. However, every section of a tubule need not be occluded by a cast, for only one small segment of a tubule need be obstructed theoretically in order to interfere with the function of the individual nephron. In a section of kidney parenchyma a single nephron is cut across in literally hundreds of places. Nevertheless, tubular cell injury is the predominant lesion microscopically in some transfusion reactions.^{5, 24, 45} No data are available on the number of casts nor does it seem possible to obtain such data. It is true that the number of casts in the kidneys of human cases, especially of transfusion reaction, is less than found in some of the dogs of my experiments.

The identity of the manifestations, and the lesions caused by transfusion reaction on the one hand and those caused by intravascular hemolysis of the patient's own blood cells on the other, is very important. One does not have to

look for some strange effect from the transfused blood, such as foreign protein or allergy or isoagglutinin effects. The changes are attributable to the hemolysis itself and hence to the products liberated from hemolyzed red blood cells.

The type of solution does not alter the effect of hemoglobinemia. Severe renal damage was produced by a solution of hemoglobin made from hemoglobin crystals in two out of three dogs. With comparable amounts of hemoglobin (over 5.0 Gm. per kilogram) hemolyzed red blood cell solutions also produced serious renal damage in three out of four dogs. The crystalline hemoglobin solution was made according to the directions of Bing¹¹ who found no impairment of renal function as measured by creatinine and para-aminohippuric acid clearances but who gave much smaller amounts of hemoglobin. The renal damage produced by the two types of solution cannot be distinguished by histologic examination of biopsy or autopsy specimens.

The possible deleterious effect of potassium in the solution can be excluded in these dogs for two reasons. In the first place, Kerr⁵⁷ has shown conclusively that the potassium content of dog red blood cells is no greater for practical purposes than that of dog serum. In the second place, administration of a solution of washed crystals of hemoglobin would eliminate any soluble crystalloid.

The most important single index of the probability of development of renal damage in the dogs I studied was the initial plasma hemoglobin level (Graph II). All dogs which developed serious renal insufficiency had values above 3.7 Gm. per 100 c.c. immediately after completing the injection of hemoglobin. Only Dog 8 had an initial level less than 3.7 Gm. per 100 c.c. and it developed only moderate renal damage. An evidence of the importance of the amount of hemoglobin in causing renal damage is the fact that five out of seven dogs given more than 5.0 Gm. hemoglobin per kilogram developed renal damage. Dog 4 was given less than this amount and developed renal damage but had an initial hemoglobin level above 3.7 Gm. per 100 cubic centimeters.

Whether or not oxyhemoglobin alone is the responsible agent cannot be answered from these experiments. In Experiment 10b the methemoglobin concentration and the total hemoglobin concentration were determined in all plasma samples and in the original solution. The plasma methemoglobin levels ranged from 0.704 to 0.530 Gm. per 100 cubic centimeters. The hemoglobin solution administered contained 13 per cent methemoglobin. The methemoglobin could be demonstrated easily by spectroscopy in all plasma samples studied in this experiment. It should be noted that methemoglobin appeared in the urine immediately in this experiment, but in other dogs with alkaline urine it never appeared until after an initial period of five to ten hours of observation. In the other experiments neither the hemoglobin solution nor the initial plasma specimen had enough methemoglobin to be visible by spectroscopy. It is probable, however, that methemoglobin was present in amounts less than that required for spectroscopic identification. As little as 3 per cent of total hemoglobin pigments can be identified as methemoglobin by spectroscopy.⁵⁷

Bing¹¹ concluded that methemoglobin was the toxic agent in hemoglobinemic states only when the urine is acid. The absence of renal damage in dogs without

acidosis does not account for the results in Experiment 10b nor in the other experiments on dogs with an alkaline urine. Methemoglobin has not been found to exist in the plasma of patients who have undergone a hemolytic transfusion reaction or developed blackwater fever.^{32, 34, 39} Methemoglobin has been found in the plasma of patients with hemolytic crisis from sulfonamides,³⁷ but it is probable that the sulfonamide had a direct effect in the production of methemoglobin. It does not seem possible at present to decide what importance should be ascribed to methemoglobin as the noxious agent in hemolytic conditions. Unfortunately, quantitative determinations were not made in any but the last experiment; however, in this instance it was known that methemoglobin was present in large quantities by spectroscopic examination before injecting the solution. In previous experiments equally diligent search failed to demonstrate any methemoglobin by spectroscopy. Methemoglobin in the urine is not the cause of the renal insufficiency, *per se*. In Dogs 5, 6, and 7 (Experiment 7a) no renal insufficiency developed though methemoglobin was recognized in the urine from the time of the first few hours. On the other hand, methemoglobin did not appear in the urine of Dogs 3, 4, or 8 in the same period, in sufficient amount to be recognized spectroscopically, and yet renal damage occurred in these dogs.

There is some evidence from clinical cases to support the thesis that the plasma hemoglobin level and/or the amount of hemoglobin liberated are the important factors. Bordley¹³ reviewed fifteen cases of hemolytic transfusion reactions. He found that the five patients who recovered received an average of 314 c.c. of blood. Ten patients who died received an average of 564 cubic centimeters. No patient receiving less than 350 c.c. died and none receiving more than 540 c.c. recovered. There have been reports of deaths occurring almost immediately after administering less than 100 c.c. of blood,⁹² but such cases may well have a different significance than those developing renal insufficiency after transfusion reaction.

In cases of hemolytic transfusion reaction which I previously³⁶ reported the only patient who developed anuria was one who had the highest level of hemoglobin a day after the transfusions. In the protocols of patients with blackwater fever reported by Foy and Kondi,⁵⁹ Fairley and Bromfield,³¹ and Yorke and associates⁹⁵ the patients with the highest plasma levels were the ones who developed oliguria and anuria. In the cases of hemolytic anemia with hemoglobinuria described by Fox and Ottenberg³⁷ one patient had a plasma level of 1.6 Gm. per 100 cubic centimeters. This patient died from pneumonia but had complete urinary suppression as a result of the hemoglobinuria. Another patient who died also had renal insufficiency. The plasma level of this patient was much lower than that of the patient with pneumonia and was comparable to levels in the two patients who recovered. No statement is made as to the time relationship of the individual values to onset of hemolytic anemia, so one cannot use the second case as evidence for or against the thesis.

Another important factor becomes apparent in the study of paroxysmal nocturnal hemoglobinuria. Whenever the plasma hemoglobin levels in patients

with this malady have been determined they have been relatively low. The highest recorded level which could be found was 288 mg. per 100 cubic centimeters.⁵² Renal damage is not a feature of the disease.⁵³ It is probable that the amount of hemoglobin liberated is usually not sufficient to raise the level dangerously. Renal damage or death from anuria is not mentioned in a review of paroxysmal cold hemoglobinuria.⁶⁴

The relationship of the reaction of the urine to development of renal insufficiency was the original purpose of the thesis. The original plan of conducting serial renal biopsies was to determine whether precipitation of hemoglobin occurs only when the urine is acid. The discussion of the pathologic findings in Dogs 3, 4, 8, and 10b is sufficient to refute this idea. The severest renal damage occurred in Dogs 9 and 11 with acid urine and Dog 10b with alkaline urine. Serious renal insufficiency and renal damage occurred in Dog 3 with plasma hemoglobin and total dose comparable to Dog 9; however, the dog was recovering but was still azotemic when it died of pneumonia at forty-six days. Dog 8 with an alkaline urine developed moderately severe renal damage and insufficiency when given a dose comparable to Dog 7 with an acid urine. Dog 7 did not develop renal damage. The urine in Experiment 5 was so nearly neutral that it probably should be excluded from the present discussion of relationship of urine reaction. Two animals with acid urine (Dogs 6 and 7a) and two with alkaline urine (Dogs 7b and 10a) did not develop renal damage from hemoglobinemia. From these experiments it is impossible to say categorically that alkalinizing the urine does not benefit any dog or that acidifying the urine does not harm any dog. Alkalinizing the urine certainly does not prevent the formation of hemoglobin casts in the kidney and does not prevent serious renal damage in all dogs. Under comparable conditions the dogs with acid urine and those with alkaline urine fared equally well or equally poorly, as the case may be. Severe and even fatal transfusion reactions can occur when the urine has been previously alkalinized.^{14, 25} In crush injuries¹⁷ the benefit of alkalinizing the urine has not been definitely established but may have merit.

The results of DeGowin and co-workers^{23, 24} are not strictly comparable to these experiments. The dogs given the acid diet may have had urine with lower pH (pH values not recorded), and their dogs with alkaline urine actually had neutral or slightly acid urine at times and slightly alkaline urine at other times. Some of the dogs with alkaline urine developed uremia of considerable proportions but recovered. Another difference is that their dogs were not anesthetized.

Cohn and Edsall¹⁹ have summarized the available information regarding the solubility of hemoglobin in relation to pH. The isoelectric point of hemoglobin is pH 6.6. The solubility of hemoglobin is at its minimum at this pH. Sodium and potassium chloride do not lead to a marked decrease in the solubility of hemoglobin or albumin in their saturated solutions. Sodium sulfate is one of the most effective salting out agents. Horse and dog hemoglobin are less soluble than human hemoglobin. This information, of course, does not take into consideration the possible effect of methemoglobin or hematin formation in acid

urine, but it is important to realize that hemoglobin is least soluble at about pH 6.5. Insufficient observations were made on the presence or absence of the manifestations of shock which may have occurred in some of the dogs. The influence of shock induced by continuous administration of histamine²⁸ for one-half to one hour is an interesting observation. No functional impairment of the kidney could be detected in spite of continuous anuria for the period of lowered blood pressure. Observations of the urine flow in the present study indicate that at no time during the first eight hours after injection did the blood pressure drop low enough to cause complete cessation of urine flow. Renal blood flow may have decreased enough to allow excessive concentration of urine in the tubules.

Yuile and co-workers²⁷ have recently reported results of some very important studies on the effect of preliminary ischemia on renal damage due to hemoglobin. They injected hemoglobin solutions in doses ranging from 1.25 to 2.32 Gm. into rabbits weighing from 2.15 to 3.2 kilograms. When the tubules of the kidneys had been previously damaged by a short period of complete ischemia or the administration of sodium tartrate, hemoglobin precipitated in the tubules of the damaged kidneys but not in normal kidneys. When the urine was acid hemoglobin casts were numerous and persistent and were associated with renal functional disturbances, in contrast to the lack of such disturbances when the urine was alkaline. These observations may have an important bearing on the puzzling problem of the relation of shock and anoxia to the development of the crush syndrome, "transfusion kidney," and related lesions.

SUMMARY AND CONCLUSIONS

A method of obtaining serial biopsies of the same kidney of a dog has been described. By explanting one or both kidneys to the subcutaneous space of the lumbar region the kidney becomes available for biopsy with a needle biopsy apparatus or for obtaining blood samples from the renal veins. Satisfactory biopsies were obtained. It is suggested that the technique may be used to advantage for studying other problems related to experimental injury of the kidney by various agents.

When 1 Gm. of hemoglobin or more per kilogram of body weight is injected into dogs, 25 to 40 per cent is excreted by the kidney. The remaining hemoglobin is destroyed in the reticulo-endothelial system or the circulating blood with the production of bilirubin and hemosiderin. When excretion and hemodilution are corrected for, the rate of disappearance of hemoglobin is found to be more uniform during the first eight hours than is apparent from the plasma hemoglobin concentrations alone. In other words, hemoglobin is destroyed at a fairly uniform rate by the dog.

The amount of hemoglobin excreted is approximately the same when the urine is alkaline as when it is acid. This is true with relatively large doses of hemoglobin and at comparable plasma hemoglobin concentrations. There are considerable variations in maximum concentrations of hemoglobin in the urine of dogs with comparable doses and plasma concentrations.

In all dogs which developed renal insufficiency, the following two pathologic findings occurred together: (1) A large number of hemoglobin casts appeared in the loops of Henle and distal tubular segments, especially in the corticomedullary portion. The casts persisted for a long time after cessation of hemoglobinuria. The majority of tubules were occluded by casts in dogs with serious or fatal renal damage. (2) Degeneration of the tubular epithelium occurred as early as four hours, reaching a maximum at five to seven days. If the dog lived longer, gradual regeneration with eventual return to normal architecture ensued. The results of the histologic observations agree with reports of other investigators, with the exception that dogs with alkaline urine had renal damage approximately as severe as those with acid urine.

The most important indices as to development of renal damage in the dogs observed were the initial plasma hemoglobin concentration and the average of the initial and twenty-four hour plasma hemoglobin concentrations. When the initial concentration was over 3.7 Gm. per 100 c.c. of plasma or the average of the two concentrations was over 2.2 Gm. per 100 c.c., renal insufficiency developed. Dogs with values below these levels all recovered without signs of permanent renal damage due to hemoglobinuria. The renal damage was just as severe when solutions of hemoglobin crystals were used as when centrifuged solutions of washed hemolyzed red blood cells were used in similar amounts and providing comparable plasma hemoglobin concentrations. The evidence obtained in this study did not offer support for Bing's belief that the renal injury is due to methemoglobin, neither did it wholly exclude this possibility.

None of the dogs developed anuria. Renal damage was manifested by an elevation of blood urea nitrogen, albuminuria, and excretion of urine of low fixed specific gravity. Casts were found in the urine during the period of hemoglobinuria in all dogs regardless of the urine pH. Casts were also found in the urine of dogs with renal damage after cessation of hemoglobinuria.

The author wishes to express his appreciation for: the constant help and encouragement in planning and carrying out the experiments and the helpful criticism of the manuscript by Dr. C. J. Watson and Dr. G. T. Evans; the criticism of the manuscript by Dr. E. T. Bell; the help of Dr. Fred Kolouch with the technique of explanting the kidney; the original suggestion of explanting the kidney by Dr. F. W. Hoffbauer; and the technical assistance of Miss Donna Mac Simpson.

THE TREATMENT OF PERNICIOUS AND RELATED ANEMIAS WITH SYNTHETIC FOLIC ACID

I. OBSERVATIONS ON THE MAINTENANCE OF A NORMAL HEMATOLOGIC STATUS AND ON THE OCCURRENCE OF COMBINED SYSTEM DISEASE AT THE END OF ONE YEAR

CARL F. VILTER, M.D., AND RICHARD W. VILTER, M.D., CINCINNATI, OHIO,
AND TOM D. SPIES, M.D., BIRMINGHAM, ALA.

THE synthetic *Lactobacillus casei* factor (pteroylglutamic acid), commonly known as folic acid, is acknowledged a potent agent in causing hematologic remissions in pernicious anemia and related macrocytic anemias.¹⁻⁵ These include the macrocytic anemias of sprue, pregnancy, and nutritional macrocytic anemia. Many clinical and biochemical problems arose following the initial hematologic experiments. The present study was undertaken in November, 1945, to answer two of the clinical questions: (1) Will folic acid control the anemia of pernicious anemia and sprue for long periods of time as successfully as liver extract? (2) Will folic acid prevent the development of the neurologic manifestations of pernicious anemia or control them after they have appeared? A long period of observation is required to obtain the answers. This article constitutes a progress report at the end of the first year of investigation.

MATERIAL AND METHODS

The twenty-eight subjects comprising the group studied were patients from the medical wards and dispensary, Cincinnati General Hospital, and patients referred to us by private physicians, usually because of sensitivity to liver extract. Twenty-one patients had pernicious anemia which had been controlled satisfactorily from two to seventeen years by injection of liver extract; three had pernicious anemia in relapse; two had sprue which had been poorly controlled by liver extract; one had nutritional macrocytic anemia; and one had macrocytic anemia and diarrhea secondary to an ileosigmoidostomy performed in 1937. Pernicious anemia was diagnosed by the following findings: macrocytic hyperchromic anemia, leucopenia, polymorphonuclear leucocyte hypersegmentation, thrombocytopenia, megaloblastic arrest of the erythrocyte series in the bone marrow, and absence of free hydrochloric acid in the gastric secretion after histamine stimulation on at least two occasions. The diagnosis of sprue was made by the presence of steatorrhea, flat glucose tolerance curve, hypocalcemia, macrocytic anemia, megaloblastic arrest of the erythrocytes in the bone marrow, free hydrochloric acid in the gastric juice after histamine, and absence of evidence for pancreatic insufficiency. The patient with nutritional macrocytic anemia had free HCl in the gastric secretions and a megaloblastic type of bone marrow and for many years had eaten a diet deficient in protein and vitamins of the B complex. Fifteen of the twenty-four subjects with pernicious anemia

From the Department of Internal Medicine, University of Cincinnati College of Medicine.
These studies were aided by a grant from the Lederle Laboratories, Inc., Pearl River, N. Y.

Acknowledgments are made to the following: Miss Virginia Hawkins, R.N., who supervised treatments in the homes; Miss Georgia Gwinner and Miss Mary Sax, hematology technicians; Dr. Oscar Berghausen, Dr. Frank Rogers, Dr. Moses Salzer, and Dr. Hiram Weiss, for their cooperation in admitting patients to this study; and Dr. Charles D. Aring, who performed many of the initial neurologic evaluations.

Presented in part at the annual meeting of the Central Society for Clinical Research, Chicago, Ill., Nov. 1 and 2, 1946.

Received for publication, Jan. 22, 1947.

had had disease of the posterior columns, lateral columns, or peripheral nerves at some time in the past, but in only one instance was there any evidence of active neurologic disease when folic acid therapy was begun. Folic acid was given orally to each patient, usually in doses of 30 mg. three times a week but in several instances in doses as low as 10 mg. or as high as 50 mg. daily. Patients were visited in their homes to insure that the medication was taken as directed. All liver therapy was discontinued but no attempt was made to modify the usual diets of the patients in their homes. Those who were brought into the hospital in relapse or for special study were given a diet from which meat, liver, and glandular products were excluded.

Complete medical and neurologic histories were obtained and physical and neurologic examinations performed on each subject at the beginning of the study. The examinations were repeated every three months, or more often if the condition of the patient demanded it. Erythrocyte and white blood cell counts were done on peripheral blood with equipment certified by the United States Bureau of Standards. Hemoglobin was determined as acid hematin using the Klett photoelectric colorimeter; hematocrit determinations were made on oxalated venous blood (4 mg. potassium oxalate and 6 mg. ammonium oxalate per 5 c.c.) by the method of Wintrobe,⁹ and reticulocyte and platelet counts were made by the wet technique using Dameshek's method.¹⁰ All hematologic tests were performed daily while the patients were hospitalized and biweekly or monthly while they were followed in the clinic. Sternal bone marrow aspirations were performed on all patients who were observed in hematologic relapse. Cover slip preparations for cytologic study of peripheral blood and bone marrow were stained with Wright-Giemsa stain.

Analysis of the gastric secretions after histamine stimulation was performed in each patient included in this study.

HEMATOLOGIC OBSERVATIONS

Seventeen of the twenty-one subjects with pernicious anemia in remission who received folic acid for approximately one year were maintained in a hematologic state equivalent to that achieved previously by adequate amounts of refined liver extract (Table I). In Cases 1 and 2 there was a fall in the erythrocytes and hemoglobin after nine to twelve months and in Cases 3 and 7 there was an increase. Minor fluctuations in the hematologic values occurred in all patients. Inspection of the statistical data for all twenty-one patients revealed no significant change for the group in erythrocytes and hemoglobin over the values at the beginning of folic acid therapy. Most of the patients noted an increase in appetite and weight. Three subjects with pernicious anemia in relapse (Cases 21, 23, and 24) had satisfactory initial hematologic responses following administration of 10 mg. folic acid daily. Two of the patients (Case 23, Fig. 1 and protocol and Case 21, Fig. 2 and protocol) were not maintained in remission on this dose, and as neurologic symptoms developed they required increasingly larger doses of folic acid to maintain the hematologic remission. The third patient with pernicious anemia in relapse (Case 24, Fig. 3 and protocol) treated with 10 mg. folic acid daily had a satisfactory hematologic remission following a peak reticulocytosis of 26 per cent on the eighth day and has maintained this remission for twelve months on 50 mg. daily.

The subject with nutritional macrocytic anemia (Case 27) received 10 mg. folic acid orally per day for four months. Reticulocytes rose to 11.6 per cent on the fifth day of treatment and erythrocytes and hemoglobin increased gradually from 2.6 millions per cubic millimeter and 14.3 Gm. per 100 c.c. to 4.7 millions and 15.7 Gm. in four months. Although folic acid therapy was discontinued

NG 63 ? PERNICIOUS ANEMIA, 1 YEAR

Fig. 1.

Case 23.—N. G., a 63-year-old white woman, had anorexia and mild dyspepsia for a year and had lost 25 pounds in weight. There were no neurologic symptoms. The dietary excluded milk and eggs and the patient seldom ate meat.

Physical examination revealed only pallor of the mucous membranes, a waxy color of the skin, and a few red papillae at the tip of the tongue. There were no neurologic abnormalities.

Laboratory studies on March 19, 1946, showed: erythrocytes, 1.57 millions; hemoglobin, 7.2 Gm.; leucocytes, 4,950; reticulocytes, 1.6 per cent; platelets, 314,000; mean corpuscular volume, 121; mean corpuscular hemoglobin, 46; mean corpuscular hemoglobin concentration, 38; a normal leucocyte differential count; bone marrow, megaloblastic arrest of the erythrocyte series; normal gastrointestinal series; histamine refractory achlorhydria.

Folic acid orally, 5 mg. per day for eleven days, was begun on March 19, 1946. On the twelfth day, March 31, 1946, the dose of folic acid was increased to 10 mg. daily and maintained for approximately two months. In five weeks (April 25, 1946) the erythrocytes were 3.31 millions, the hemoglobin 13.8 grams. The patient felt entirely well, and although redness of the papillae of the tip of the tongue waxed and waned there was no soreness. The appetite was excellent and there was a weight gain of 22 pounds. After two months (May 19, 1946) hematologic values had fallen slightly and a neurologic examination showed: hyperactive knee and ankle jerks, positive Romberg sign, and slight reduction of vibration perception at the ankles. The only subjective complaint was of attacks of weakness in the right leg. The dose of folic acid was increased at this time to 50 mg. orally daily. There was a gradual

(Continued on opposite page.)

after four months, the patient's diet was improved to include foods rich in "extrinsic factor(s)." Three months after discontinuing folic acid there has been no relapse and none is to be expected.

The two subjects with sprue (Cases 25 and 26) were maintained in normal hematologic equilibrium. Remarkable improvement in diarrhea which had not been controlled by liver extract was noted in Case 26. Bowel movements decreased from five to six daily to one daily and weight increased from 127 to 147 pounds in two months. When folic acid therapy was discontinued for three months, mild glossitis appeared but cleared rapidly when folic acid therapy was reinstituted. The second subject with sprue (Case 25) continued in a satisfactory state of remission and the weight increased from 119 to 126 pounds.

The patient with macrocytic anemia secondary to ileosigmoidostomy (Case 28) was maintained in as normal a hematologic state by folic acid therapy as by crude and refined liver extract therapy. This person had had six to eight bowel movements daily since 1937 in spite of liver extract and was weak and distressed by abdominal distention. After three months of folic acid therapy the bowel movements had decreased to three daily, the weight had increased from 131 to 136 pounds, abdominal distention was partially relieved, and the patient was able again to play eighteen holes of golf without fatigue. (The improvement of a diarrhea essentially of a mechanical variety was not expected and no explanation is evident. Maintenance of a normal blood picture, however, suggests efficient absorption of folic acid from the small intestine.)

NEUROLOGIC OBSERVATIONS

Only one patient had subjective complaints or objective evidence of active central or peripheral nervous system degeneration prior to the administration of folic acid. This patient (Case 24, Fig. 3 and protocol) had numbness and

rise in erythrocytes and hemoglobin during the next months (July 13, 1946) to 4.16 millions and 14.2 Gm., respectively. Within a week of the discovery of positive neurologic signs the patient noticed numbness and tingling in the hands and feet and unsteady gait. The neurologic signs and symptoms progressed rapidly in spite of a final increase in the dose of folic acid to 250 mg. orally daily for two weeks (Aug. 13, 1946). The patient was afraid to get out of bed for fear of falling. Numbness and tingling in the hands and feet were severe. Examination showed ataxia in arms and legs, hypalgesia over hands and feet, vibration perception 50 per cent reduced at the ankles and knees and 25 per cent in the fingers, and perception of position slightly reduced in the toes, deep reflexes hyperactive and the snout reflex positive; there were no plantar reversal signs or clonus.

At this point five months after continuous therapy with folic acid in increasing dosage and after a slight fall in erythrocytes and hemoglobin to 3.57 millions and 12.8 Gm., respectively, folic acid was discontinued (Aug. 27, 1946). Refined liver extract, 50 U.S.P. units, was administered intramuscularly daily for two weeks and twice weekly thereafter. In two weeks the patient felt much better. The paresthesias had almost disappeared. She walked well but with steppage gait. The Romberg test was normal, and there was no ataxia. Pain, light touch, temperature, and position perception were normal. Vibration perception improved but after six weeks of liver therapy was still reduced approximately 30 per cent at the ankles, 20 per cent at the knees, and 10 per cent in the fingers. The deep reflexes remained hyperactive. All redness disappeared from the tongue. The erythrocytes and hemoglobin rose very slowly in six weeks to 4.13 millions and 14.1 Gm., respectively.

M.V. 59 ♀ PERNICIOUS ANEMIA 10 YEARS

Fig. 2.

Case 21.—M. V., a 59-year-old white woman, had Addisonian pernicious anemia of ten years' duration. Treatment with liver extract had been sporadic because of hypersensitivity reactions. Symptoms of relapse were weakness, pallor, and anorexia. On Jan. 15, 1946, she had received a hypodermic injection which was said to be iron cacodylate.

The patient was small, thin, and pallid. Glossal papillae were atrophied. There was no evidence of brain, spinal cord, or peripheral nerve disease.

Laboratory studies revealed: histamine refractory achlorhydria; normal gastrointestinal series; erythrocytes, 1.07 millions; hemoglobin, "less than 6 Gm.," white blood cell count, 6,250.

Course: On Jan. 12, 1946, folic acid 10 mg. orally daily was begun. The blood picture improved and was well maintained on 10 mg. folic acid through the fifth month. At that time, however, stiffness in the knees and numbness and tingling in the fingers occurred. Examination showed: Romberg positive, ataxia in the legs, pain and light touch sensations preserved, position perception impaired in the toes, and vibration not felt at the ankles and approximately 75 per cent reduced at the knees. The patient left town without notice but had a supply of folic acid adequate for 10 mg. daily for two months. She returned at the end of this period unable to walk without assistance. She had evidently taken the folic acid but the exact amount could not be determined. Mental deterioration was obvious. The patient seldom completed a sentence and her memory was poor.

Examination showed: pallor, a few red papillae at the tongue tip; motor weakness at the ankles and knees; vibration perception absent at the knees and ankles, reduced in pelvis, normal in hands; perception of position of the toes absent; marked ataxia in the legs and ankle clonus; knee and ankle jerks hyperactive; and plantar reversal signs positive. Erythrocytes were 2.59 millions, hemoglobin 10 grams. The bone marrow showed moderate megaloblastic arrest in the erythroid series. The patient was hospitalized and given 250 mg. folic acid twice daily for twelve days. There was a moderate reticulocytosis to 8.6 per cent on the sixth day and a slight increase in erythrocytes but no change in the neurologic disease. Refined liver extract, 50 U.S.P. units daily for seven days and then every other day, induced neurologic improvement in ten days (disappearance of clonus and a normal Chaddock

(Continued on opposite page.)

tingling in the hands and feet, stocking type of hypesthesia to touch, and pin prick and diminished knee and ankle reflexes, interpreted as signs of peripheral neuritis. While receiving folic acid, 10 mg. daily, the signs of peripheral neuritis increased. Remission or progression in these signs could not be correlated with increases or decreases in the dosage of folic acid and for the last nine months the patient's complaints and neurologic abnormalities have been essentially the same as when treatment was begun.*

After five to eight months on folic acid therapy, four subjects with pernicious anemia (Cases 20 to 23) noted the gradual onset of numbness and tingling sensations in the hands and feet, unsteadiness of gait, and moderate stiffness in the extremities. Neurologic signs appeared after the hematologic status had reached or was near normal and gradually progressed until there was definite evidence of combined system disease. The neurologic abnormalities implicated the posterior columns and peripheral nerves in four of the subjects, lateral columns in three, and cerebral cortex in one subject. None of these persons had neurologic involvement of any type when pernicious anemia was diagnosed initially or when folic acid therapy was begun. When signs of nervous system degeneration were unequivocal, usually indicated by the appearance of a positive Romberg sign, the extensor response on plantar stimulation, loss of sense of position and of perception of vibration in the feet, and hypesthesia and hypalgesia in fingers and toes, each of these four patients received 50 to 500 mg. folic acid orally per day for ten to forty days. These large doses of folic acid resulted in no subjective or objective improvement. Refined liver extract (10 U.S.P. units per cubic centimeter), 3 to 5 c.c. given intramuscularly per day, was begun after it was obvious that amelioration of the neurologic signs and symptoms would not occur or when progression of the disease was so rapid as to endanger the patient's future well-being. Within ten days thereafter improvement in the neurologic status began. The dose of liver extract was reduced to 3 to 5 c.c. on alternate days, and convalescence is progressing satisfactorily in all four patients. The progression of neurologic disease in the two patients most severely affected is indicated in Figs. 1 and 2. Shown in Fig. 3, Case 24, is the course of the patient with peripheral neuritis in whom the exacerbations and remissions seemed to occur independent of folic acid treatment. Accompanying each figure is the appropriate case history.

DISCUSSION

As yet too little time has elapsed to make sweeping statements regarding the effectiveness of folic acid as maintenance therapy for the patient with pernicious

response). In two months she was clear mentally and could walk without aid but with a wide base. All plantar reversal signs had disappeared. There was slight swaying with the Romberg test. The position of the toes was perceived after maximal stimulation. Vibration was perceived at the knees but not at the ankles. The erythrocyte count and hemoglobin had gradually increased to 4.26 millions and 14.4 Gm., respectively.

*Since this article was submitted for publication this patient has developed definite posterolateral sclerosis, has been treated intensively with liver extract, and has shown a moderate remission.

M.V. 59 ♀ PERNICIOUS ANEMIA 10 YEARS

Fig. 2.

Case #1.—M. V., a 59-year-old white woman, had Addisonian pernicious anemia of ten years' duration. Treatment with liver extract had been sporadic because of hypersensitivity reactions. Symptoms of relapse were weakness, pallor, and anorexia. On Jan. 15, 1946, she had received a hypodermic injection which was said to be iron cacodylate.

The patient was small, thin, and pallid. Glossal papillae were atrophied. There was no evidence of brain, spinal cord, or peripheral nerve disease.

Laboratory studies revealed: histamine refractory achlorhydria; normal gastrointestinal series; erythrocytes, 1.07 millions; hemoglobin, "less than 6 Gm.," white blood cell count, 6,250.

Course: On Jan. 12, 1946, folic acid 10 mg. orally daily was begun. The blood picture improved and was well maintained on 10 mg. folic acid through the fifth month. At that time, however, stiffness in the knees and numbness and tingling in the fingers occurred. Examination showed: Romberg positive, ataxia in the legs, pain and light touch sensations preserved, position perception impaired in the toes, and vibration not felt at the ankles and approximately 75 per cent reduced at the knees. The patient left town without notice but had a supply of folic acid adequate for 10 mg. daily for two months. She returned at the end of this period unable to walk without assistance. She had evidently taken the folic acid but the exact amount could not be determined. Mental deterioration was obvious. The patient seldom completed a sentence and her memory was poor.

Examination showed: pallor, a few red papillae at the tongue tip; motor weakness at the ankles and knees; vibration perception absent at the knees and ankles, reduced in pelvis, normal in hands; perception of position of the toes absent; marked ataxia in the legs and ankle clonus; knee and ankle jerks hyperactive; and plantar reversal signs positive. Erythrocytes were 2.59 millions, hemoglobin 10 grams. The bone marrow showed moderate megaloblastic arrest in the erythroid series. The patient was hospitalized and given 250 mg. folic acid twice daily for twelve days. There was a moderate reticulocytosis to 8.6 per cent on the sixth day and a slight increase in erythrocytes but no change in the neurologic disease. Refined liver extract, 50 U.S.P. units daily for seven days and then every other day, induced neurologic improvement in ten days (disappearance of clonus and a normal Chaddock

(Continued on opposite page.)

anemia. It is impossible to predict how long a patient who has had adequate treatment with liver extract previously may go untreated without suffering a relapse.¹¹ The length of time before relapse depends upon such variables as the amount of stored erythrocyte maturation factor, the amount of intrinsic factor (however minute) produced by the stomach, the amount of extrinsic factor(s) in the diet, and the occurrence of infections and degenerative diseases. It is a well-known fact that adequately treated patients with pernicious anemia may suffer relapses within two to six months after liver extract is discontinued or they may remain in good health for as long as fifteen years.¹² Observations over a period of one year fall far short of being optimal; yet, considering the size of the group they suggest that folic acid will, in most cases, maintain the hematologic remission initiated by itself or by liver extract. There is no obvious mechanism to explain the fall in erythrocyte counts and hemoglobin levels in several of the patients. There was no evidence of infection or abnormality other than pernicious anemia in these patients and no obvious change in diets or activities. The amount of folic acid which previously had induced a remission in Cases 21 and 23 later seemed to be decreasingly effective in these same patients. Speculations on the mechanisms behind this are possible but too presumptive.

It is evident that folic acid did not prevent the occurrence of combined system disease, nor did massive doses halt or reverse the degenerative process once it had begun. Liver extract on the other hand bettered the neurologic status. These observations augment the single case of treatment failure of combined system disease reported by Moore¹³ at the 1946 Meeting of the Society for Clinical Investigation and similar observations of Bethel¹⁴ and Hall¹⁵ and their associates. They confirm the many rumors that synthetic folic acid has proved disappointing in combined system disease. On the other hand, Doan⁸ has reported one subject with mild neurologic abnormalities which disappeared during therapy with folic acid. The statement is made that "Minor neurologic signs and symptoms in patients in relapse have responded as promptly and completely following *L. casei* factor supplements as with potent liver extract, and no progressive cord lesions have as yet been noted."

Similar differences of opinion were recorded from 1927 to 1935, when the effect of liver extract in combined system disease was under close scrutiny.

millions, the hemoglobin 11.1 grams. At this time (Dec. 17, 1945) there was proximal extension of hypesthesia in the hands and appearance of stocking hypesthesia in the legs. On Jan. 31, 1946, when the erythrocyte count was 4.19 millions and hemoglobin 13.0 Gm., further extension of signs of peripheral neuritis were noted. Folic acid was again increased to 50 mg. daily and continued through Nov. 20, 1946. In five weeks the signs of neuritis had returned to the initial degree. Repeated neurologic examinations revealed no change through November, 1946. No definite signs of posterolateral sclerosis had been observed at any time and the signs of neuritis appeared and disappeared independent of folic acid therapy. In September and October, 1946, a slight fall in the hemoglobin and erythrocytes was noted and on Nov. 22, 1946, the values were erythrocytes 3.9 millions, hemoglobin 10.7 grams. This occurred during an exacerbation of bronchial asthma and continued observation is necessary for final evaluations.

F.C. 66 ♀ PERNICIOUS ANEMIA, ASTHMA

Fig. 3.

Case 24.—F. C., a 65-year-old white woman, complained of paresthesias in the hand and feet, intermittent glossitis, and progressive weakness for six weeks. Her two sister had pernicious anemia. The patient was pale and slightly icteric. The tongue was normal. Vibratory perception was impaired at knees and ankles; perception of position of the toe was intact; there was hyperalgesia and hypesthesia on the palmar surfaces of the hands; and knee jerks were hyperactive and ankle jerks hypoactive.

Laboratory data revealed: erythrocyte count, 1.22 millions; hemoglobin, 4.7 Gm.; white blood count, 1,500; packed cell volume, 15 per cent; reticulocytes, 2.0 per cent; platelets 178,120; mean corpuscular volume, 127; mean corpuscular hemoglobin, 38.6; mean corpuscular hemoglobin concentration, 30.4; megaloblastic arrest in erythrocyte series in the sternum marrow; and histamine refractory achlorhydria. X-ray studies revealed a small hiatus hernia and a duodenal diverticulum.

Synthetic folic acid, 10 mg. daily, was given orally beginning on Nov. 15, 1945. Reticulocytes began to rise on the second day and reached a peak of 26 per cent on the eighth day. In twenty days the erythrocytes and hemoglobin had risen to 1.90 millions and 7.5 Gm., respectively, and the dose of folic acid was increased to 50 mg. daily for seventeen days and then reduced to 30 mg. three times a week. In another ten days the erythrocyte count was 2.4.

Careful studies during this period presented evidence for and against the beneficial effect of liver extract on the neurologic degeneration originally recorded by Minot and Murphy.^{1a} The effectiveness of liver extract was established only after many years of careful study and control of the potency. Therefore, final opinion must await further study of the effect of folic acid in various doses and by parenteral as well as oral routes of administration. Until a factor essential to the preservation of the central and peripheral nervous systems is found and until much more is known concerning the mode of action of folic acid in hematopoiesis, liver extract will remain the safest effective agent for the routine treatment of pernicious anemia.

SUMMARY

1. Folic acid in doses of 10 to 15 mg. daily or 30 mg. three times a week given orally maintained twenty-one persons with pernicious anemia in apparent hematologic remission for one year. Three patients with pernicious anemia in whom treatment was begun during a relapse responded satisfactorily to an initial daily dose of 10 mg. folic acid, but two of them required increasing amounts daily to maintain the remission; the third patient received 50 mg. daily for most of the year to determine the effect of the drug on peripheral neuritis.

2. Folic acid given orally controlled the manifestations of sprue in two persons for one year, nutritional macrocytic anemia in one person for seven months, and macrocytic anemia secondary to ileosigmoidostomy in one person as/or more effectively than liver extract.

3. Folic acid in doses of 10 to 50 mg. daily did not prevent the development of combined system disease in four persons with pernicious anemia. After combined system disease developed, folic acid in doses of 100 to 500 mg. daily given orally did not stop its progression in these persons. Liver extract, however, promoted rapid improvement.

4. These observations suggest that an unknown factor or factors in liver other than folic acid are essential for maintaining the integrity of the central and peripheral nervous systems in persons with pernicious anemia.

5. Folic acid cannot be considered satisfactory or complete treatment for pernicious anemia and should not replace potent liver extract in the routine treatment until another method for the protection of the nervous system is devised.

°. Injected intraperitoneally.

given which remained in the liver, spleen, and lungs. Variations in concentration throughout a given organ make this estimate rather uncertain. This effect becomes evident upon inspection of the data in Table III, in which studies of gold distribution in four dogs are presented. The large variation in the estimated percentage of the dose retained by the liver is evident. In Dog 4 the concentration in liver and spleen is determined from multiple samples, and the data show a consistent picture of complete removal of gold by these organs alone. The variation in gold content of different samples of liver and spleen in Dog 4 is shown in Table IV. The distribution of manganese in liver, spleen, pancreas, and heart of two dogs is shown in Table V. Here, instead of determining the activity of random samples, entire organs were used.

STUDIES OF THE DISTRIBUTION OF INTRAVENOUSLY ADMINISTERED COLLOIDAL SOLS OF MANGANESE DIOXIDE AND GOLD IN HUMAN BEINGS AND DOGS USING RADIOACTIVE ISOTOPES

C. W. SHEPPARD, E. BUIST WELLS,* P. F. HAHN, AND JAMES P. B. GOODELL
NASHVILLE, TENN.

INTRODUCTION

RECENTLY in the course of internal radiation therapy using colloidal manganese dioxide containing radioactive manganese (Mn^{52})¹ an opportunity has been presented to study the distribution of small particles in human beings when introduced intravenously. Similar observations have been made using colloidal metallic gold containing the radioactive isotope Au^{198} . In several patients whose disease came to fatal termination it was possible to determine the radioactivity of various tissues taken at autopsy, permitting a relative comparison to be made of their concentrations of manganese or gold. Three patients also were studied whose life expectancy was a matter of hours. Here only tracer doses were given. One of these subjects received the material via the intraperitoneal route. The distribution studies in human beings were augmented by studies of distributions in dogs; a record was obtained also of the disappearance of colloidal gold from the circulation in one dog and in one human subject.

RESULTS

In Table I is shown the relative distribution of radioactivity in selected tissue samples from eleven patients who had received radioactive manganese and two who received both manganese and gold. The distributions in patients receiving both isotopes were determined under conditions where the radiation from gold had disappeared. Thus only manganese is measured. Usually several doses had been given; however, due to radioactive decay, conditions were such that almost all of the radiation was due to a particular final dose. Since all values are relative some method of common comparison is required. Thus we have expressed the results in terms of the ratio of the activity per gram of tissue (wet weight) to that of the heart (muscle). Patient 6 is of particular interest since the dose was given intraperitoneally to this subject. In Table II are shown equivalent data for two patients who received gold alone. We attribute the approximate tenfold difference in numerical results primarily to a large variation in the content of the heart muscle in the two patients. In one patient we were able to determine tissue concentrations in micrograms of gold per gram of tissue. It was possible also to estimate the percentage of the dose

From the Departments of Biochemistry and Medicine, Vanderbilt University, School of Medicine.

This research was supported in its earlier stages by a grant from the Nutrition Foundation and a special grant from the American Medical Association for the purchase of radioactive manganese. The latter part of the work was made possible through a grant from the Donner Foundation.

Received for publication, Jan. 18, 1947.

*Now in the United States Navy Medical Corps.

In Patient 14 results are expressed in counts per minute per gram of tissue relative to heart muscle taken as unity.

In Patient 15 concentrations in micrograms per Gram of tissue are given and estimates of the total fraction of the initial dose in certain organs are calculated.

THE COLLOIDAL SOLS

The manganese dioxide dispersions were prepared by oxidizing manganous chloride with potassium permanganate. Gelatin was used as the supporting colloid. The method has been described previously in more detail.¹ The sols were not dialyzed and there is some evidence that a small fraction of undispersed crystalloidal manganese is present.² Although precise determination of particle size was not made in each case, frequent microscopic observations of these dispersions using dark-field illumination showed that they were ultramicroscopic in size and exhibited a vigorous Brownian movement. In one case a sol was prepared for electron microscopy and a picture was taken.* The distribution in size of the particles of this sol was determined from the electron micrographs and is shown in Fig. 1. The second maximum may be due to the interaction of excess permanganate with gelatin. In all cases these sols had a deep brown color when observed by transmitted light and a greenish cast under reflected light.

In the animal experiments quantities of the order of 5 mg. of gold or less could be dispersed with good control of particle size. The sols were prepared by reducing a solution of gold chloride with ascorbic acid. Due to the instability of ionic gold and the presence of excess ascorbic acid, the gold dispersal should certainly be complete. Although gelatin was used, it is not essential. At pH 3 to 5 a characteristic dispersion was obtained containing relatively large particles. Such a sol was pale blue by transmitted light and had a heavy brick-colored blush under reflected light. The Tyndall beam was strong and an appreciable fraction of the scattered light was unpolarized. Under dark-field illumination the particles exhibited a relatively sluggish Brownian motion. The

*Electron microscopy was kindly done by Dr. H. C. O'Brien, Department of Physics, University of Pittsburgh.

ADMINISTRATION

Sols were given to the patients via the cubital vein. In most instances an isotonic saline infusion was first begun. The material was added to the infusion and washed in with further saline. In a few cases the sols were given directly by syringe. In one case serial blood samples were taken immediately following injection and at short intervals for about one hour thereafter. The disappearance of gold from the circulation is shown in Figs. 2 and 3. The pertinent clinical data for the patients studied are shown in Table VI. The number of milligrams of material given and the intervals between the last dose and autopsy are included.

Fig. 1.—Distribution in particle size of a typical manganese dioxide sol.

The dogs were injected via the jugular vein. In all cases female mongrel animals were used. The animals were untrained and were not in a controlled state of nutrition. The animal weights, duration of life after injection, and type of sol given in each case are given in Table VII. In the case of gold each animal (Dogs 1 to 4) received the same total amount of gold, namely, 4 milligrams. A disappearance curve for one dog who received a gold sol of the large particle type is shown in Figs. 4 and 5.

TABLE IV. VARIATION IN GOLD CONCENTRATION IN LIVER AND SPLEEN OF ONE DOG

LOCATION OF SAMPLE	CONCENTRATION
Liver—tip of right central lobe	8.0
Liver—center of right central lobe	11.6
Liver—top of right central lobe	16.1
Liver—center of lobus quadratus	10.7
Liver—center of left central lobe	13.3
Liver—center of left lobe	12.6
Liver—center of left lobus Spigelii	12.6
Liver—center of right lobe	11.4
Spleen—extreme dorsal end	9.9
Spleen—one-third of total length from dorsal end	9.0
Spleen—one-third of total length from ventral end	11.2
Spleen—extreme ventral end	13.1

The notation is that of Ellenburger and Baum.²

Concentrations are in micrograms of gold per gram of tissue.

All spleen sections, 1 cm. thick, are taken transverse to the major axis of the organ.

TABLE V. DISTRIBUTION OF RADIOACTIVE MANGANESE IN DOGS

ORGAN	DOG 5			DOG 6		
	ACTIVITY	PER CENT INITIAL DOSE	RATIO TO HEART	ACTIVITY	PER CENT INITIAL DOSE	RATIO TO HEART
Liver	11.8	55.0	11.0	9.6	48.0	12.0

Activities are in counts per minute per gram.

particles were easily thrown out of solution by centrifuging under an acceleration of about 2,000 grams. A sol of this type will be referred to as a large particle sol. Under alkaline conditions (pH 8 to 10) the sols had a characteristically different appearance. They were both red by transmitted light and exhibited little or no blush. The Tyndall beam was faint but was highly polarized. Under dark-field illumination the particles showed a violent Brownian motion and could not be removed from suspension by centrifuging. This sol will be called the small particle sol. Dark-field comparison of samples of the two sols having equal concentrations of gold showed that the small particle sol contained by far the greatest average number of particles per unit volume. Electron microscope pictures of the particles in both of these sols were obtained. These pictures showed that the particles were uniform in size and roughly spheroidal in shape. The large particles were about $200\text{ m}\mu$ in size and the small ones about one-fifth to one-tenth as large.

In therapy larger amounts of gold were dispersed at one time. Here the close control of particle size was not attained, but by adjusting the pH rough control was still possible. The therapeutic sols were dispersed under alkaline conditions and contained particles which were on the whole similar to those of the small particle sols. The color to transmitted light was initially reddish violet similar to that of blackberry juice. As time proceeded the color changed to a deeper red. Dark-field studies indicated a greater spread in particle size but a predominance of small particles. It was repeatedly verified that gold sols can be autoclaved at will. Once dispersed they maintain full stability under widely varying conditions of temperature, pH, and salt content.

RADIOACTIVE ISOTOPES AND MEASUREMENTS OF RADIOACTIVITY

The radioactive manganese* contained principally Mn^{52} of half-life 6.5 days. Small amounts of Mn^{54} were present. Since this isotope has a 310-day half-life, distribution data could be obtained at considerable time after the last dose of manganese. The radioactive gold† was the 2.7-day isotope Au^{198} . No long-lived activity was found after more than ten half-lives of decay.

Fig. 3.

Fig. 2.—Disappearance of a therapeutic gold sol from the circulation of a human patient. (Time is measured from the end of the injection period.)

Fig. 3.—Semilogarithmic plot of the data shown in Fig. 2.

At autopsy fresh tissue samples were taken, weighed, dried overnight at 105°C . and then dry ashed in a muffle furnace at 600 to 700° centigrade. A second ashing was frequently required in order to reduce the level of carbonaceous material to a negligible amount in the sample. In the case of manganese dioxide the ash was dissolved in HCl , hydrogen peroxide was added to reduce the manganese, and then each sample was transferred to a small metal

ointment tin⁴ and dried. In some cases carrier manganese was added; however, no significant difference was found between samples in which this addition was made and others. In a limited number of cases check determinations of the gamma ray activity of samples were made before and after transfer from the beakers in which the ashing was conducted. Transfer was found to be complete, and negligible quantities were left behind. In the case of radioactive gold, nonradioactive gold chloride was added to the samples as a carrier in all cases. After ashing, the gold was taken into solution by adding a few drops of aqua regia. Excess acid was removed by heating before transfer was made to the enps. In the studies of disappearance of radioactivity from the circulation, the blood samples were dried directly in the enps and counted.

Fig. 4.

Fig. 5.

Fig. 4.—Disappearance of a large particle gold sol from the circulation of a dog. (Time is measured from the end of the injection period.)

Fig. 5.—Semilogarithmic plot of the data shown in Fig. 4.

Radioactivity measurements were made with the usual thin mica window bell-type Geiger-Müller counter. In the majority of cases the counting tube was connected to a counting-rate meter of the M.I.T. type. In other instances a scaling circuit was employed. Radioactivity was calculated in arbitrary counts per minute per gram of fresh tissue. By determining the activities of tissues at considerable time after autopsy, manganese could be traced in patients who received both elements, since the short-lived gold had then decayed to a negligible level, leaving only the 310-day isotope of manganese

5	8.0	24 hr.	Manganese dioxide sol
6	9.0	24 hr.	Manganese dioxide sol
7	8.4	48 hr.	Crystalloidal $MnCl_2$ solution

DISCUSSION

Drinker and Shaw⁵ injected finely divided manganese dioxide intravenously into cats. Their dispersions were prepared by centrifugation and were probably not of uniform particle size. The particles were less than 1μ in size and were thus small enough to traverse the capillary circulation. The sols were stabilized by adding gum acacia. The disappearance of particles from the circulation was rapid, and in the majority of cases manganese was not found in the blood eighteen minutes after injection. At autopsy 47 per cent of the injected manganese was found in the lung. The content of the liver was 38.3 per cent, of the spleen 4.3 per cent, and of all other organs 10 per cent. Histologic studies indicated that the particles were located within or upon the lining of the capillary endothelium, suggesting that they were not strained out by the capillary bed of the lung by simple filtration. In a separate study Lund, Shaw, and Drinker⁶ showed that the cat was unique in this behavior and that rabbits, dogs, guinea pigs, rats, chickens, and turtles concentrated the material predominantly in the liver alone. The content of the spleen was always of the order of 1 or 2 per cent of the initial dose. No separate investigation of the pancreas was conducted.

Since these results suggest that species differences can occur, one could not predict human distribution results with any confidence using our different type of sol prior to the present investigation. The data in Table I are obtained only from single samples of the organs. Only pathologic cases have been studied and absolute percentages of the initial injected dose of manganese in each organ have not been obtained for obvious technical reasons. Nevertheless, the results are similar to those of the previous investigators who use laboratory animals. Thus, we can state with some confidence that the distribution of colloidal manganese in human beings is essentially the same, even when smaller particles are used or smaller amounts of manganese. We hesitate to attach any significance to the lower percentage found in the livers of the two dogs compared to those of the earlier workers, since in our method of preparation an appreciable non-dispersed crystalloidal fraction may have been present. Previous experiments have indicated that this is rapidly excreted.² The relative amounts are in good agreement with the earlier work.

The high concentration of radioactivity in the pancreas is of great interest. Examination of the data presented by Reiman and Minot⁷ shows that the normal human pancreas contains a relatively high concentration of manganese, being

TABLE VIII. DISTRIBUTION OF CRYSTALLOIDAL MANGANESE IN ONE ANIMAL (Dog 7)

ORGAN	COUNTS PER MINUTE PER GRAM	RATIO OF CONCENTRATION TO HEART	PER CENT DOSE
Pancreas	120	7.5	0.02
Liver	180	11.0	1.50
Spleen	19	1.2	0.005
Heart	16	1.0	-
Gall bladder bile	270	17.0	-

exceeded only by the liver. Since the pancreas does not concentrate colloidal gold it is suspected that the manganese in the pancreas was derived, at least in part, from ionic manganese. In a single exploratory experiment an injection of ionic manganous chloride tagged with Mn^{54} was given to a dog. The distribution of tagged manganese in liver (multiple samples), spleen and pancreas (entire organs), and heart is shown in Table VIII. The gall bladder contents were rich in tagged manganese as might be expected from the known biliary excretion of the crystalloidal element. Although this experiment does not prove that all of the manganese in the pancreas was derived from ionic manganese, the high pancreatic concentration is suggestive. A complete understanding of the pancreatic concentration must await experiments with dialyzed colloids and further studies of the metabolism of ionic manganese. It is possible that manganese may play a more significant role in pancreatic metabolism than previously has been realized.

It was noted in Table I that the patients lived for variable intervals after the last dose. This dose in nearly all cases contributed almost entirely to the radioactivity at autopsy. There appears to be no really significant change in relative concentration of radioactivity as the elapsed time following the last injection increases. Nevertheless, the values are subject to rather large variations which may obscure small effects.

The doses which were administered were always small. In the case of gold less than 3 mg. were given to a typical patient. In the case of manganese the maximum dose was 3.8 mg. of metallic manganese equivalent (Patient 9), and the majority of doses varied between 0.3 and 1 milligram. Here again the data do not give any picture of variation of distribution with the size of the dose.

It is shown in Fig. 2 that colloidal gold disappears rapidly from the human circulation and that under proper conditions the semilogarithmic plot (Fig. 3) is strictly linear for a considerable period of time. The appreciable time for injection (two or three minutes) plus the short interval before the first blood sample was obtained (one and one-half minutes) is evidently ample to insure circulatory mixing. The exponential decay with a "half-life" of two and one-half minutes suggests that the rate of phagocytosis is strictly proportional to the concentration of colloidal particles in circulation. The disappearance curve for the dog (Figs. 4 and 5) indicates a correspondingly rapid decline. The nonlinearity of the disappearance curve suggests that the dog was not in a uniform circulatory state. Since the animal was not trained and struggled frequently during the experiment, this was not surprising.

The distribution of colloidal gold in different samples of liver and spleen in Dog 4 indicates a systematic variation (Table IV). The activity of equivalent central samples of each lobe is essentially the same, but a systematic increase in concentration is indicated between the peripheral and central portion of the right central lobe in which multiple samples were taken. Similarly, there was a significant variation in the concentration of gold in the spleen samples. Bearing this in mind, it is not difficult to understand the definite variations in comparative results in all cases where determinations were made on single samples of tissue. In spite of such variations, however, the picture is consistent in that liver and spleen are roughly equivalent in concentration of radioactivity and outstandingly high compared to all other tissues. This distribution is very similar to that found by Jones, Wrobel, and Lyons⁸ in a single dog which received an intravenous injection of colloidal chromic phosphate containing particles $1\ \mu$ or less in size.

The different splenic concentrations for gold and manganese is noteworthy indeed. If we are concerned with true phagocytosis, there must be a characteristic difference between the phagocytic action of the spleen for different chemical substances, such that the affinity of the spleen for manganese dioxide is relatively less than for gold. It is of interest that Voigt⁹ observed a relatively lower concentration of colloidal silver in the spleen of the rabbit.

Although only one intraperitoneal injection was given, it is of considerable interest that the distribution is roughly similar to that obtained by intravenous injection. Additional research is required before definite conclusions can be established in this matter.

SUMMARY

A study of the relative distribution of colloidal particles of manganese dioxide containing radioactive Mn^{52} has shown that in the human being liver concentration is high. The concentration of the pancreas and kidney is intermediate and that of the spleen and other organs is low. Two dogs showed a similar picture for liver, pancreas, spleen, and heart, which were the only organs studied. Studies in human subjects and dogs of the distribution of colloidal gold containing radioactive Au^{198} showed a high concentration in liver and spleen, intermediate to low in the kidney, and a low concentration in other organs. The difference in the splenic concentration of gold and manganese is striking and suggests a fundamental difference of phagocytic activity for the two substances. The high pancreatic concentration of manganese is of especial significance.

We wish to thank the various members of the Department of Pathology at Vanderbilt University School of Medicine who helped in obtaining autopsy specimens. The assistance of many other staff members also is gratefully acknowledged.

EFFECT OF PREGNANCY ON THE COMPLEMENT OF GUINEA PIGS

E. E. ECKER, C. W. HIATT, AND L. M. BARR
CLEVELAND, OHIO

ALTHOUGH it is generally known among serologists that the serum of a pregnant guinea pig is likely to be unsatisfactory for use in complement fixation, no study of the exact relationship between pregnancy and complement in this animal has been found in the literature. The question is of importance as a preliminary step in the study of complement variations in disease, since some knowledge of the possible variations of complement in different physiologic states is necessary for the proper interpretation of data obtained from a group of experimental animals. The present study was undertaken in an attempt to delineate the range of variation of complement in pregnant guinea pigs.

METHODS

Selection and Care of the Animals.—A group of nine healthy adult guinea pigs, known to be nonpregnant, was selected as a control in the experiment. Members of the group ranged in age from 10 to 14 months and in weight from 450 to 700 grams.

The group of pregnant guinea pigs was composed of females recently bred or known to be pregnant. The group was screened to exclude any animals that did not correspond approximately to the control group in respect to age, size, and general health. Various stages of pregnancy were represented in the group, particularly the later stages. A total of fourteen animals was observed both during and after parturition. Two additional animals were acquired after they had given birth and were observed only during the postparturition period.

All animals were maintained separately in clean, dry cages. They were fed a controlled diet of oats, Rockland guinea pig Pellets, dried alfalfa, and fresh cabbage. No water was offered to the animals at any time.

The time of parturition of each pregnant guinea pig was recorded from actual observation or from an estimate based on the appearance of the litter after birth had occurred.

Method of Obtaining Blood Samples.—A blood sample of 0.4 to 0.6 c.c. was withdrawn twice weekly from each guinea pig by bleeding from a small incision in the marginal vein of the ear. This method appears to have no undesirable effects upon the animal and, for that reason, is to be preferred to the more common method of cardiac puncture, particularly in a study of this type.

The blood sample was collected in a clean 3 c.c. serologic test tube, covered with a small piece of parafilm to protect the sample and retard evaporation,

From the Institute of Pathology, Western Reserve University, and the University Hospitals.

Aided by a grant from the Commonwealth Fund.

Received for publication, Dec. 11, 1945.

allowed to clot for twenty minutes at 2 to 4° C., and then centrifuged at 1,600 r.p.m. for fifteen minutes. The supernatant serum was decanted carefully into another clean 3 c.e. test tube and stored at 2 to 4° C. until used. In all cases the serum was titrated within two hours after collection of the sample.

Method of Titration.—The assay of complement was performed by a method independently devised in this laboratory. Similar methods have been used by Mayer, Eaton, and Heidelberger¹ and by Kent, Bukantz, and Rein.²

The serum to be tested was diluted 1:100 in 0.9 per cent saline solution. Immediately after dilution, portions of the diluted serum were pipetted into each of three clear glass test tubes (of the type designed for use in the Klett-Summerson photoelectric colorimeter). For sera of a high titer, the portions used were 1.00, 1.50, and 2.00 c.e., respectively. For sera of low titer, portions of 1.50, 2.00, and 2.50 c.e. were used. Varying the quantities in this fashion provided an optimal amount of serum in at least two of the three tubes. The volume in each tube was adjusted to 2.50 c.e. by the addition of saline solution.

To each tube 2.50 c.e. of a suspension of sensitized sheep red cells (prepared as herein described) were then added. The tubes were shaken thoroughly and incubated for thirty minutes at 37° Centigrade. After the incubation period, the tubes were centrifuged at 1,600 r.p.m. for five minutes.

The color of the supernatant fluid in each tube was measured with a Klett-Summerson photoelectric colorimeter equipped with a standard green filter over the light source. The scale of the instrument is calibrated in units which are proportional to the concentration of dissolved hemoglobin in the supernatant layer. Thus, the per cent hemolysis occurring in a given tube may be computed as the ratio of the color reading to that of the supernatant layer in a completely hemolyzed sample. The latter value was determined for each set of titrations by taking the color reading of 2.50 c.e. of the sensitized cell suspension laked in 2.50 c.e. of distilled water.

Preparation of the Standard Sheep Cell Suspension.—One volume of freshly drawn packed sheep erythrocytes was washed four times in 10 volumes of saline solution. The washed, packed cells were suspended in saline solution in sufficient amount so that a sample of this suspension (diluted 1:20 in saline solution) gave a color reading of 280 on the colorimeter. When thus adjusted in concentration, the cell suspension was then diluted with an equal volume of saline solution containing 5 units of rabbit antisheep hemolysin of a titer of at least 1:4,000. After mixture of the cells and hemolysin, the suspension was allowed to stand for thirty minutes at 2 to 4° C. before use. The final suspension contained about 2 per cent (by volume) of packed cells and approximately 2.5×10^8 erythrocytes per cubic centimeter.

Calculation of Results.—The amount of 1:100 serum required to effect 50 per cent hemolysis was obtained from a form of the von Krogh equation (3):

$$x = k \left(\frac{y}{1 - y} \right)^{1/n}$$

Where x equals amount of hemolytic serum, y equals fraction of total cells hemolyzed, and k and $1/n$ are constants for a given set of experimental conditions. When expressed in the logarithmic form and adapted to the case of 50 per cent hemolysis, the equation may be written as:

$$x_2 = \text{antilog} \left(\log x_1 - \frac{1}{n} \log \frac{Y}{100 - Y} \right)$$

Where x_2 equals cubic centimeters of 1:100 serum required for 50 per cent hemolysis, x_1 equals cubic centimeters of 1:100 serum actually used, and Y equals per cent hemolysis actually obtained. For the titration used, the value of the constant $1/n$ was found to be $0.22 \pm .02$. Curves of x_2 versus $\frac{Y}{100 - Y}$

were plotted on log-log graph paper for the various discrete values of x_1 . From the resulting straight-line nomograph, the value of x_2 for any values of x_1 and Y could be determined by interpolation.

The von Krogh equation is a satisfactory empirical statement of the relationship only when the hemolysis is between 10 and 90 per cent. The serum portions (x_1) have been chosen so that the resulting hemolysis will ordinarily be within this range. In this experiment the value of x_2 was taken as the average found in the tubes (usually all three) in which more than 10 but less than 90 per cent hemolysis occurred.

The *complement activity* was defined arbitrarily as the number of 50 per cent hemolytic units per cubic centimeter of serum. In terms of x_2 this is expressed as:

$$\text{Complement activity} = \frac{100}{x_2}$$

Complement activity bears a direct relationship to the concentration of complement in the serum and provides a convenient figure for graphing and tabulation.

RESULTS AND DISCUSSION

The results of 262 separate complement titrations are shown as a "scatter diagram" in Fig. 1. Complement activity is depicted as a function of time in days relative to the date of parturition. For the nonpregnant guinea pigs, the distribution of points along the time axis was in terms of the number of days before or after the middle of the observation period.

Inspection of the graph apparently discloses that (1) the pregnant guinea pigs had substantially lower complement activities than the nonpregnant ones and (2) the postparturition period in the group of pregnant guinea pigs was marked by a gradual increase in complement activity.

These observations may be further substantiated by statistical analysis.* The average complement activity for each nonpregnant guinea pig is shown

*The authors are indebted to Dr. Huldah Baneroft, Department of Preventive Medicine, Medical School, Western Reserve University, for assistance in the statistical evaluation.

TABLE I. COMPLEMENT ACTIVITY IN NONPREGNANT GUINEA PIGS

in Table I; the average complement activities for the pregnant animals, both before and after parturition, are shown in Table II. The animals were divided into three groups: nonpregnant, ante partum, and post partum. The statistical significance of the differences among the means of complement activity in the three groups was determined by the method devised by Fisher⁴ for groups small in number.

The results of the statistical analysis are shown in Table III. The value of "t" in the tests of significance are well above the minimum values required to demonstrate significant differences among the three groups.

Fig. 1.—Scatter diagram of complement activity before and after parturition. Points for the nonpregnant group are located according to the number of days before or after the middle day of the observation period.

It should be pointed out that, although a significant difference in complement activity between the nonpregnant and post-partum groups exists, the gradual upward trend in the post-partum group predicts that most of these animals would have returned to normal within five weeks after parturition. This prediction is confirmed by the frequent observation of the authors that the serum

$$\dagger t = \frac{|\bar{x}_1 - \bar{x}_2|}{s} \sqrt{\frac{n_1 n_2}{n_1 + n_2}}$$

of a female guinea pig four to six weeks after parturition is fully as active in fixation and hemolysis as the sera of adult virgin female guinea pigs kept under the same dietary conditions.

CONCLUSIONS

1. Pregnancy in the guinea pig is accompanied by a substantial decrease in complement activity of the serum.
2. After parturition complement activity gradually increases toward the level normal for nonpregnant female guinea pigs.

TOXICITY STUDIES OF α (4-HYDROXY-3,5-DIODO-BENZYL-N-BUTYRIC ACID) AND α (4-HYDROXY-3,5-DIODO-BENZYL-N-CAPROIC ACID): COMPOUNDS PROPOSED AS GALL BLADDER CONTRAST AGENTS

DAVID M. GRAYZEL AND SAMUEL NATELSON
BROOKLYN, N. Y.

VISUALIZATION of the gall bladder through the use of a new series of compounds has been described in a recent report.* Of these α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid) and α (4-hydroxy-3,5-diiodo-benzyl-n-caproic acid) were selected as having superior properties from the point of view of concentration in the gall bladder with a minimum of reaction of the patient. Since these compounds may be used extensively in clinical work it was deemed advisable to undertake a study of their toxicity.

Both substances appear as fine, white crystalline powders. They are insoluble in water but soluble as the sodium salts. Through the use of sodium hydroxide α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid) forms a solution with a pH of 7.5, while under similar conditions α (4-hydroxy-3,5-diiodo-benzyl-n-caproic acid) forms a solution of pH 8.5. The compounds were purified before use by dissolving them in 5 per cent NaHCO_3 solution (1 Gm. to 100 c.c. of bicarbonate solution). Charcoal was added and the solution filtered. The acids, precipitated by the addition of concentrated hydrochloric acid, were filtered and, after drying, recrystallized from carbon tetrachloride.

EXPERIMENTAL PROCEDURE

For intravenous administration a 25 per cent solution of each compound was used. For oral use the powder was intimately mixed with small amounts of ground red meat or fish. In all experiments cats of 2.5 to 4 kilograms of body weight were used. These cats were observed for a period of one week before starting the experiments.

During the experiment the weights of each animal were recorded frequently and their general behavior and reaction to the drugs were observed. The cats were then sacrificed at the termination of the period of observation, which varied from two to six weeks. Necropsy studies then were made.

DISCUSSION OF RESULTS

Administration of these drugs to cats by the oral route causes much less evidence of toxic effects than is the case with intravenous administration. With the exception of an impaired appetite for a period of forty-eight hours, the cats showed no untoward reaction to the oral administration of the drugs. Vomiting was not observed at any time and all the animals gained weight. During the period of observation two of the cats delivered normal litters of kittens. At

neecropsy there were no abnormal findings either in the gross or in histologic sections, except that a minimal degree of cloudy swelling was noted in the liver and kidneys of two cats.

No estimation was made of the lethal dose orally, because all animals survived doses of 1,000 mg. per kilogram of body weight. Higher doses were not studied, for the total dose administered to human beings orally does not exceed 100 mg. per kilogram of body weight.

8a	305	1,325	6	Convulsions; rapid breathing; coma; recovered in 24 hours
10a	315	1,025	4	Convulsions lasting for about 1 hour; coma; recovered after 24 hours
11a	335	1,250	6	Rapid respirations; coma; twitchings; fully recovered in 24 hours
15a	375	750	-	Violent convulsions; coma; died after 15 minutes

Study of α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid), in intravenous doses below 200 mg. per kilogram, failed to demonstrate any abnormal reactions. Above this level the administration of the drug caused convulsions, rapid respiration, and varying degrees of drowsiness; such reactions were more marked above 300 mg. per kilogram. When 400 mg. per kilogram were administered intravenously the cats became comatose, and at 500 mg. per kilogram death followed after a coma of forty-five minutes' duration. The lethal intravenous dose of this drug is of the order of 400 to 500 mg. per kilogram.

Following the intravenous studies of α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid), the intravenous studies of α (hydroxy-3,5-diiodo-benzyl-n-caproic acid)

were started at a level exceeding 200 mg. per kilogram of body weight. At levels of 200 to 275 mg. per kilogram rapid respiration was noted, together with some ataxia and twitchings of the extremities. At 300 mg. per kilogram convulsions were observed, and at 315 mg. per kilogram the convulsions were marked, with rapid breathing. This rapid breathing persisted for several hours. When the dose was raised to 375 mg. per kilogram death of the injected animal occurred after fifteen minutes.

The animals that survived the intravenous administration of the drugs recovered completely after twenty-four to forty-eight hours. They took their feeding well thereafter and gained weight. When the animals were sacrificed at the end of two to four weeks no abnormal findings were observed on gross examination of the liver and kidneys.

In the two animals that died following the administration of the lethal doses, petechial hemorrhages were noted in the lungs. The livers and kidneys showed moderate degrees of cloudy swelling.

SUMMARY

1. The toxic effects of α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid) and α (4-hydroxy-3,5-diiodo-benzyl-n-caproic acid) were studied, both by oral and by intravenous administration, in a total of forty-two cats.

2. Oral administrations of the drug were tolerated in doses up to 1,000 mg. per kilogram, without vomiting. Appetite was impaired for forty-eight hours.

3. The intravenous administration of α (4-hydroxy-3,5-diiodo-benzyl-n-butyric acid) caused convulsions in doses higher than 200 mg. per kilogram and death at 500 mg. per kilogram. Intravenous administration of α (4-hydroxy-3,5-diiodo-benzyl-n-caproic acid) caused convulsions at 200 mg. per kilogram and death at 375 mg. per kilogram.

4. All the animals given sublethal doses of the drugs recovered completely and gained weight at the end of two to four weeks.

5. Necropsy studies revealed no abnormal findings, except in cats which were given lethal doses of the drugs. In these cats petechiae in the lungs and cloudy swelling in the liver and kidneys were found.

LABORATORY METHODS

THE MICROCOLORIMÉTRIC ESTIMATION OF PLASMA PROTEINS

ANTHONY A. ALBANESE, BARBARA SAUR, AND VIRGINIA IRBY
NEW YORK, N. Y.

IN A recent publication¹ we described a colorimetric method utilizing the Sakaguchi reaction for the estimation of total proteins and protein fractions in human plasma, nephrotic urine, and abdominal fluid in terms of arginine which was shown to have an accuracy comparable to the micro-Kjeldahl method. Subsequent experiments have shown that because of the relatively negligible nonprotein arginine content of the blood greater economy of time and blood sample without appreciable loss of accuracy can be achieved by: (1) determination of total plasma proteins on a 1 c.c. aliquot of a sample prepared by diluting 0.1 c.c. of plasma to 2 c.c. volume with 10 per cent NaOH instead of an alkaline solution of the trichloroacetic acid precipitated proteins, (2) estimation of albumin and globulin by direct measurement of both proteins as arginine in fraction derived from the same 0.2 c.c. sample of plasma rather than by difference of total protein and globulin, and (3) elimination of the three-hour incubation period usually employed in the separation of albumin and globulin fractions of the plasma. The rapidity and ease of operation which has been gained by these modifications would seem to recommend the method for routine clinical work.

EXPERIMENTAL

Reagents.—

Sodium Hypochlorite: A 0.06 N solution was prepared as needed from the commercially available Clorox. The necessary dilution of the stock product was ascertained iodometrically as follows: To 1 c.c. of Clorox in a 125 c.c. Erlenmeyer flask are added 25 c.c. of chlorine-free water in which has been dissolved 1 Gm. of potassium iodide. The mixture was then titrated with 0.1 N sodium thiosulfate, 1 c.c. of starch indicator being used. The stock product has been found to be fairly stable for three to four months if kept in the refrigerator in a brown bottle.

Sodium Hydroxide: A 10 per cent solution.

Urea: A 20 per cent solution.

α -Naphthol: One hundred milligrams of the resublimed product are dissolved in 100 c.c. of 95 per cent ethanol. The solution is kept in a brown bottle and stored in the refrigerator.

Arginine Standard: One (plus) arginine hydrochloride* (26.6 per cent N found), 12.05 mg., is weighed accurately and dissolved in 100 c.c. of a saturated aqueous solution of benzoic acid. One cubic centimeter of this solution is equivalent to 100 γ of the free base. This solution is stored in the refrigerator.

Ether: Reagent grade can be used as obtained.

Sodium Sulfate, Anhydrous: A 22 per cent solution is employed and is stored in a 37° C. incubator.

From the Department of Pediatrics, New York University College of Medicine, and the Children's Medical Service, Bellevue Hospital.

Received for publication, Nov. 8, 1946.

Analytic Procedures.—

Total Plasma Proteins: One-tenth cubic centimeter of plasma (derived from blood collected over lithium oxalate) in a graduated 15 c.c. conical centrifuge tube was made to the 2 c.c. mark with 10 per cent NaOH. A 1 c.c. aliquot of the thoroughly mixed sample was transferred to a graduated colorimeter tube, and 5 c.c. of water and 1 c.c. of alcoholic naphthol were added in rapid succession. After standing for five minutes, 1 c.c. of sodium hypochlorite is added, followed exactly one minute later by the addition of 2 c.c. of 20 per cent urea solution. The resulting solutions are mixed by inverting the tubes and read in the Klett-Summers colorimeter with Filter S-54 after a lapse of five minutes. The color intensity of the test mixture has been found to remain constant for an hour or more after the initial reaction period, so that there is no need to hasten the color measurement. A parallel determination is also done on a 1 c.c. aliquot of the standard and a reagent blank.

Plasma Albumin and Globulin: To 0.2 c.c. of plasma in a 50 c.c. round bottom, small neck centrifuge tube (A. H. Thomas No. 3123) was added with mixing 7 c.c. of 22 per cent sodium sulfate and then 3 c.c. of ethyl ether.² This mixture was shaken vigorously for two minutes and then centrifuged at 3,000 r.p.m. for ten minutes. The globulin which collected at the ether-water interface was separated from both liquid layers by careful decantation into a 25 c.c. graduated cylinder. The volume of the aqueous, albumin-containing fraction was adjusted to 10 c.c. by the addition of water, and a 5 c.c. aliquot of this layer is removed by pipette to a 10 c.c. graduated colorimeter tube. Subsequent to the addition of 1 c.c. of 10 per cent NaOH, the protein content is determined in terms of arginine described as follows.

The disk of precipitated globulin was dissolved in 2 c.c. of 10 per cent NaOH and then 2 c.c. of water were added. Gentle heating of the mixture in a hot water bath drives off the residual ether and thereby greatly facilitates solution of the protein. A 2 c.c. aliquot of the cooled sample was transferred to a colorimeter tube and submitted to the Sakaguchi reaction after the addition of 4 c.c. of water.

The alkaline dilution of the whole or fractionated plasma of specimens containing 400 mg. per cent of cholesterol or more should be shaken with 5 c.c. of ether prior to removal of sample for the arginine determination.

Attention is called to the fact that in all revisions of sample size which different circumstances may necessitate, it is imperative that the sample be contained in a 6 c.c. volume which shall include the equivalent of 1 c.c. of 10 per cent NaOH prior to the addition of the other reagents.

Calculations: After the colorimeter is set to zero for the reagent blank, the arginine present in the protein samples is estimated by comparison with the value of the arginine standard. The protein equivalent is obtained by multiplying the arginine values by the dilution factors and 19.2, a factor derived from the mean arginine content of human plasma albumin and globulin.³

RESULTS

The possibility of the present modification of our previously described method for the determination of plasma proteins was impressed upon us by the finding that protein-free filtrates obtained from 5 c.c. samples of ten different human plasma gave negative Sakaguchi tests. This observation indicated that failure to separate the proteins from whole plasma would not introduce any appreciable errors in the final values.

Our experiments amply confirmed the observations of Kingsley² that when ether is employed in conjunction with sodium sulfate no preliminary incubation period is required for the separation of globulin and albumin. It has also been found that serum or plasma derived by the use of other oxalates or other anti-coagulants can be used with this method.

The total plasma values obtained by the usual micro-Kjeldahl method and three variants of the arginine method are listed in Table I. It will be noted

TABLE I. COMPARISON OF TOTAL PLASMA PROTEIN VALUES OBTAINED BY VARIOUS TECHNIQUES

SPECIMENS	MICRO-KJELDAHL METHOD, PROTEIN = $N \times 6.25$ (GM. %)	ARGININE METHOD, PROTEIN = ARGININE $\times 19.2$		
		TRICHLOROACETIC ACID-PRECIPITATED PROTEIN (GM. %)	PLASMA DILUTION (GM. %)	TOTAL PLASMA PROTEIN = ALBUMIN + GLOBULIN (GM. %)
Ka, normal, 2 years	7.65	7.70	7.66	7.73
Ec, nephrotic, 1.5 years	3.80	3.84	3.80	3.93
As, nephrotic, 2 years	5.75	5.74	5.78	5.78
Sa, nephrotic, 3 years	4.48	4.46	4.57	4.58

that the figures obtained by the two techniques described in the present report, dilution of the whole plasma and addition of the individually determined albumin and globulin values, are in good accord with those obtained with the arginine method utilizing the trichloroacetic acid-precipitated plasma proteins as well as those of the micro-Kjeldahl procedure.

COMMENT

The accuracy, speed of operation, and economy of sample achieved by the present modification of the arginine method for the determination of plasma proteins would seem to favor its adoption for routine or clinical studies. Although these procedures are somewhat more involved and time consuming than the specific gravity methods,⁴ the higher degree of accuracy which they afford makes the additional effort which they entail seem worth while. This is especially true of the copper sulfate method which has recently been shown by Adams and Ballou⁵ to exhibit such poor correlation between the specific gravity measurement and protein content as determined by the micro-Kjeldahl procedure as to make it valueless as a measure of total serum proteins of the blood. This and similar findings reported by Looney⁶ and Zozaya,⁷ however, have been contradicted by the observations of Atchley and co-workers.⁸ The biuret method of Kingsley² which is also rapid and employs only small amounts of plasma proved unsatisfactory in our hands. Our difficulties arose from (1) lack of stability of the alkaline copper sulfate reagent, (2) development of uncontrollable turbidity in test samples, especially with specimens from nephrotic patients, and (3) lack of consistent correlation of biuret plasma or serum values with micro-Kjeldahl figures.

Attention is called to the fact that in physiologic or pathologic hyperaminoacidemia, which would naturally tend to increase the amount of free circulating arginine, the plasma or serum proteins should be precipitated with trichloroacetic acid prior to the application of the *Sakaguchi* reaction as previously reported,¹ rather than employ the procedure described here.

SUMMARY

A rapid microcolorimetric method for the determination of total plasma proteins or plasma albumin and globulin has been described which yields values comparable to those obtained by the micro-Kjeldahl procedure.

A PULSATING PERFUSION APPARATUS

J. A. LONG*
BERKELEY, CALIF.

THIS apparatus, announced in Science,^{2a} is a considerable improvement over the one described in 1939,¹ differing in form and size, embodying some entirely new additions, yet retaining the essential features of construction of the older apparatus. Its general appearance is shown in Fig. 1, and details of construction are shown in Figs. 2 to 6. It is so planned that it can operate on a small quantity of blood and that the organ can be studied under a microscope during perfusion. With the apparatus and its specimen chamber shown in Fig. 1, the stomach, pancreas, and part of the duodenum of the rat can be perfused with whole rat blood.

In Figs. 2 to 6 only the essentials are shown. The chief portion of the apparatus consists of a number of pieces of $\frac{1}{8}$ inch plate glass, the largest (Plates I and II) measuring $4\frac{3}{8}$ by 7 inches, held together by twelve bolts and milled nuts. The latter are not shown in the drawings given, but in Fig. 5 their positions are indicated. Most of the other essential parts are fabricated from glass tubing and are attached to the plates by ground taper joints.

The channels or "vessels" through which the blood or other fluid circulates consist of small holes drilled through the plates and half-round grooves cut in one plate and covered by another. Most of these grooves are on the under side of the second plate (II) from the bottom; some are in other plates as shown in the drawings. The arrangement or plan of these channels and their relations to the reservoir and pump and other parts are shown in Fig. 5. Some appear in section in Fig. 6.

The essential parts of the pump are two valve chambers, two valves, the three rubber tubes and bulbs, connecting channels, and the electromagnet and mechanism for compressing the middle tube (No. 2). The valve chambers are large holes cut in the middle plate (IV) of the three making up the pump. The valves are small triangular disks of glass (Figs. 3, 5, 6), one of which rests on the openings in the bottom of each chamber. The "cylinder" is tube No. 2, and the "piston" of the pump is the fluid in tube No. 2, which moves up and down as the rubber tube is rhythmically compressed by the magnet and its attached mechanism and released to expand by its own elasticity. The connecting channels (2 and 3) are between the valve chambers and the "cylinder." Channel 1 carries blood to and Channel 4 carries blood away from the chambers. The action of the valves and the direction of flow is easily seen, by reference to Figs. 5 and 6, to be that of an ordinary pump with the arrangement such as to propel the blood in the direction of the arrows.

Received for publication, Jan. 21, 1947.

*Institute of Experimental Biology, University of California.

Tubes 1 and 3 are attached by short channels (12 and 13) to the valve chambers. All three tubes are furnished with pinchcocks. The pinchcock on Tube No. 2 is close to the plates by which the tubes are compressed and is kept closed during the operation of the pump. The pinchcocks on Tubes Nos. 1 and 3 are adjustable as to height. On No. 1 it is kept low except when the tube is being compressed as an aid in filling the chamber. Tube No. 3 serves to modify the impulse given to the blood. When the pinchcock is low the blood is propelled in short violent spurts; as it is raised higher and higher the rubber tube by its cushionlike elasticity more and more softens and prolongs the spurts, until a continuous pulsating flow may be obtained without reducing the total pressure.

The intermittent current for energizing the magnet is produced by interrupting a direct current by means of a mercury switch carried by a pendulum, or by any suitable mechanism, so adjusted that the time is equally divided between compression and release.

The reservoir is shaped as shown in order to reduce to a minimum the area on which blood corpuscles might stagnate and also to keep down the volume of blood necessary to operate the apparatus. The lower narrow part of the reservoir holds about 8 c.c.; since about 4 c.c. of blood is required to fill the pump chambers and all the channels, operation can be carried on with a minimum of about 5 c.c., although it is safer to use 8 to 10 cubic centimeters. (A rat donor weighing 500 grams furnishes sufficient blood for one experiment.) Around the reservoir and the return tubes is placed a larger cylinder fitted into a tapered groove for protection. It can serve as a reservoir in case larger quantities of fluid are required.

For oxygenating the blood the upper wide part of the reservoir is employed. When a small organ is being perfused it is sufficient to fill this part of the reservoir with small glass balls and to allow the returning blood to trickle over them, while at the same time oxygen released below rises between the balls to come into contact with the blood. However, when a large volume of blood is to be oxygenated, as in the perfusion of the stomach, pancreas, and part of the duodenum, a more efficient yet simple method had to be devised. This is shown in Fig. 1. It consists of a pair of windshieldlike wipers of rubber dam which smear over the inner surface of the wide part of the reservoir the returning blood which is directed by small pieces of stainless steel against the surface. The wipers are attached to a piece of glass tubing through which oxygen is conducted and released below the wipers. The glass tubing is fitted at its upper end with a brass sleeve which turns in a bushing in the glass cover of the outer cylinder. The sleeve carries a small gear which meshes with another gear, outside the cylinder, attached by a flexible cable to the reduction gear of a small motor. The wipers make about 20 complete rotations per minute and keep the blood spread in a thin film in direct contact with oxygen.

Blood is drawn by the pump from the reservoir through Channel 1 and is discharged through Channels 4 to 6 to the arterial spout and canula and thence into the artery of the organ. Having circulated through the vessels of the organ, it is discharged as dark venous blood through the venous canula to Channels 9 and 10 and on through the venous return tube to the top of the reservoir where

FIG 1.

FIG. 2.

reservoir. It is arterial blood and helps greatly to keep the blood in the reservoir oxygenated. By means of this control valve pressure in channels between the pump and organ can be adjusted to the optimum desired, for the pump is capable of giving a pressure of over 200 mm. of mercury. The pressure is indicated by a

FIG. 4.

mercury manometer on another side channel between Channels 5 and 7. The arrangement of the manometer is sufficiently clear in Fig. 6, where it will be seen that there is an oil trap between the blood and mercury. It may be added that

the flask containing both blood and oil can be rotated in Plate VII, the lower portion thus serving as a stopcock when it is desired to isolate the manometer from the rest of the apparatus.

It has been found that in order to have a uniform and perfectly reliable action of the pressure control valve it is necessary to place a small disk of rubber dam between the valve and valve seat. Similar disks under the valves of the pump are advantageous.

For occasions when it is necessary to reduce the pressure quickly, a slender rod is provided attached to the valve, the raising of which at once releases the pressure in channels between the pump and specimen organ. By a simple mechanism shown in Fig. 1, this release is made automatic when the pressure becomes too high. A pair of fine enameled wires is inserted in the upper part of the manometer tube, down to the mercury level allowable. The wires are connected to an electromagnet. When the rising mercury column completes the circuit through the wires, the magnet jerks the release rod sufficiently to release the pressure.

For conveniently taking blood samples for analysis from the venous return Channel 10, at 14 (Figs. 2 and 5), is a short side channel and tapered orifice for a connecting tube or spout. The latter is connected by a short rubber tube to a three-way stockcock (Fig. 1) which, with a syringe arranged for blowing out the channels, makes it possible to take samples and to empty all channels from the outlet to Channel 10 so that each sample is uncontaminated by a preceding one.

At 15 (Fig. 5) is a channel from an outside tapered orifice, furnished with a spout, to an opening in the floor of the reservoir. To the spout a graduated cylinder is attached by a rubber tube (at the left in Fig. 1) through which the reservoir can be filled, and also emptied, with a measured quantity of blood.

Of equal importance with the rest of the apparatus are the means of supporting and attaching the organs to be perfused. This is accomplished by the specimen chamber together with Plate X on which it sets and its cover. The specimen chamber is made of plaster of Paris soaked in shellac and dried. The depressions in it are shaped (as in that for the stomach, duodenum, and pancreas, shown in Fig. 1) in such fashion as to support the organs in approximately their normal topographical positions, with provision to spread part of the pancreas over a shelf just under the cover where it can be observed under a microscope and to require the minimum amount of fluid to cover them. At appropriate locations are spouts for the blood canulae and outlets for the esophagus and duodenum. These are of stainless steel and are attached to Plate X. The outlets have connections to the outside so that fluid can be introduced into the stomach and collected from the intestine. The upper ends of the spouts appear at the right in Fig. 1. They are similar to those shown in Figs. 2 to 4 and have similar connections with the channels. In the plaster is embedded a coil of nichrome wire for heating, and two holes are provided for a thermometer and a thermostat. The size and form of the chamber and the location of the spouts differ with the organ under investigation.

In Fig. 1 may be seen a rubber and glass connection between the chamber and the upper end of the reservoir. This connection serves to return to circulation blood that accumulates in the chamber from small leaks, for it is practically impossible to prevent the escape of blood from minute tears or from seepage. The amount of this leakage varies greatly, and in no case is of importance, since it does not interfere with the supply of blood to the tissues.

The whole apparatus rests on a warm plate of approximately the correct temperature. The warm plate and the heating element and the thermostat in the chamber keep the latter at a very constant degree of heat.

The plates are sealed together with paraffin introduced when the plates are hot, with the result that all the channels, except those in the pump, are lined with a film of paraffin which keeps blood from contact with the glass, an item of some importance since most of the channels are in ordinary glass. Only certain parts are of Pyrex, namely, the pump, Plate IX into which the reservoir is set, and all parts made of tubing. In the ordinary course of sealing these Pyrex parts would not get the film of paraffin. The spouts and the reservoir are usually sealed in place with a mixture of beeswax and rosin.

The whole apparatus can be completely sterilized by appropriate methods. When it is to be thoroughly cleaned it is easily taken apart in hot water, washed with soap, and finally dried from alcohol with chamois skin before being assembled in a dustproof chamber. For work which does not require aseptic precautions it is sufficient to remove only the top plate of the pump (Plate V, Figs. 3, 4, and 6), manometer and pressure control valve and their plate (VII), the reservoir and spouts, and Plate X, along with the specimen chamber, to clean them and to rinse out the remaining channels, all of which can be done in a short time. These plates when reassembled are sealed with stopcock grease.

Since the construction of the apparatus (especially the specimen chamber, the spouts, and canulae) and the technique of isolating the organs have been developed together, it is appropriate to give a brief outline of the procedure of making the preparation. All of the dissecting must be done under a binocular microscope arranged to be focused by the feet of the operator. Minute electric cauteries, which can be turned on and off and the temperature controlled by the action of the right knee, are used almost exclusively for cutting mesenteries, vessels, and other tissues. During the isolating of the organs, which requires about one and one-fourth hours, it is important that the blood supply to organs, for example the stomach, pancreas, and that part of the duodenum to which the pancreas is attached, be maintained without interruption. The canulae used are short with bulbous tips and are attached to short pieces of rubber tubing (Figs. 2 to 4) which can be slipped over the spouts. Before being inserted into the blood vessels the free ends of the rubber connections are closed with minute stainless steel plugs, and the canulae and connections are filled with a solution of heparin. These canulae are introduced and tied into the portal vein before the latter reaches the pancreas and into the aorta just caudad to the left renal artery. Ligatures are placed in readiness around the portal vein where it enters

three diuretics employed. Ascorbic acid when given prior to the administration of mercurhydrin or simultaneously with it increased the average minimal lethal dose over 50 per cent. The lethal dose of mercurpurin and of salyrgan with theophylline was not affected when combined with ascorbic acid.

Ascorbic acid previously has been noted to increase the diuretic effect of mercurpurin. A study of ten persons in congestive failure who have received mercurhydrin with ascorbic acid intravenously has revealed an equal or increased diuresis up to 50 per cent.

These investigations indicate that mercurhydrin (2 c.c.) combined with ascorbic acid (500 mg.) is the least cardiotoxic and most potent intravenous diuretic preparation studied.

DISCUSSION

DR. EDWARD MASSIE, St. Louis, Mo.—I would like to ask whether vitamin C may be given without danger in the same syringe?

DR. JOHN W. SCOTT, Lexington, Ky.—I have found clinically that the action of the mercurial diuretics can be smoothed out by giving the patient one of the B complex lyophilized preparations dissolved in the mercurial product. This makes a clear solution which has been perfectly harmless in the 100 or more instances in which I have used it.

DR. CHAPMAN.—The workers in South America have used magnesium sulfate. While their report on results so far as percentages are concerned has not been given, there was some decrease in toxicity when these products were used in combination.

We have given vitamin C and the mercurial product in the same syringe with no bad effects.

Our experience has been the same as Dr. Scott's in the use of vitamin B complex together with the mercurial substance; it does help to smooth the use of the mercurial diuretic, clinically at least.

THE SERUM PROTEIN FRACTION RESPONSIBLE FOR THE THYMOL TURBIDITY TEST

PHILIP C. COHEN, M.D., AND FRANCES THOMPSON, B.S. (BY INVITATION),
MADISON, WIS.

The thymol turbidity test of MacLagan (1944) has been shown to be of considerable diagnostic value in cases of liver disease. MacLagan stated in his paper that the test was probably due to an increase in serum gamma globulin. Recant and associates (1945), on the other hand, have shown that the test depended on the presence of a lipid-containing fraction of serum globulins rather than on the gamma globulins.

A systematic study in this laboratory of the serum protein fraction responsible for the thymol turbidity test indicates that a beta globulin is involved. A large number of fractions obtained from pooled normal human plasma were tested with the thymol reagent. High values were always associated with those fractions containing a high percentage of beta-1 globulin. Electrophoretic analysis of sera showing high thymol turbidity values invariably showed a high beta globulin level, whereas sera having normal beta globulin levels gave normal turbidity values. After mixing positive sera with thymol reagent and then dialyzing against the thymol reagent, it was possible to centrifuge off the precipitate from the supernatant and examine both in the electrophoresis ap-

paratus. The serum after treatment with thymol reagent, and free of its precipitate, differed from the untreated serum chiefly in a decrease of the beta globulin fraction to a normal level (Table I). Further, electrophoretic analysis of the precipitate after redissolving showed it to be chiefly a single protein with an electrophoretic mobility characteristic of normal beta globulins.

TABLE I. ELECTROPHORETIC ANALYSIS OF SERUM COMPONENTS BEFORE AND AFTER TREATMENT WITH THYMOL REAGENT

	PER CENT COMPOSITION				
	ALBUMIN	ALPHA-1	ALPHA-2	BETA	GAMMA
Before	47.7	4.5	9.1	19.1	19.5
After	53.3	5.5	9.1	13.0	19.0

While the beta globulin fraction of blood is known to be lipid-containing, the total lipid content of sera did not appear to be related to the thymol turbidity values. Thus, a serum from a case of lipid nephrosis with a cholesterol content of 1,400 mg. per 100 c.c. showed a negative test.

In a comparative study of cases of liver disease showing a discrepancy in the thymol turbidity and cephalin-cholesterol flocculation tests, the latter was invariably positive in cases of high gamma globulin levels and the former in cases of high beta globulin levels. In cases where both tests were positive both these fractions were elevated above normal levels. In general it was found that higher and more consistently positive thymol turbidity values were associated with acute inflammatory rather than chronic degenerative hepatic disorders.

DISCUSSION

DR. WILLIAM S. HOFFMAN, Chicago, Ill.—It would appear from Doctor Cohen's data that a positive thymol turbidity test reduces the beta globulin concentration of the serum to a level below normal. I wonder if this indicates that the positive thymol turbidity test is produced by the presence of a substance which, when thymol is added, precipitates the normal beta globulin.

BIOPSY OF LIVER IN PATIENTS WITH ACTIVE BRUCELLOSIS: DESCRIPTION OF HEPATIC LESIONS

FREDERICK W. HOFFBAUER, M.D., AND WESLEY W. SPINK, M.D.,
MINNEAPOLIS, MINN.

A review of the literature on the alterations of the tissues in patients with brucellosis indicates that the changes are widespread involving, particularly, the reticulo-endothelial system. Practically all the reports have been based upon an examination of post-mortem material. Only on rare instances have biopsies of the liver been made in living subjects. The present report is part of a study on the pathogenesis of brucellosis and represents an endeavor to define the incidence and nature of the hepatic lesions in patients with active brucellosis.

Thus far, one patient with acute brucellosis and four with the chronic form of the disease have been studied. Four of the patients were proved to have brucellosis by isolation of *Brucella abortus* from the blood stream. The fifth individual had clinical and laboratory findings consistent with chronic brucellosis. In one subject a specimen of liver was obtained by means of peritoneoscopy;

in a second individual material was acquired incidental to an abdominal operation; and in the three remaining patients biopsies were made by an operative procedure under local anesthesia.

Abnormal histologic findings were apparent in all specimens. The liver of each of the five patients showed the presence of granulomatous lesions which have been described in brucellosis. The granuloma were usually found in the liver cords rather than in the portal spaces. These lesions were composed of epithelioid cells, lymphocytes, and plasma cells arranged in small round groups. In addition, variable increases in portal connective tissue and occasional necrotic liver cells were seen.

In an endeavor to correlate the hepatic injury with liver function, multiple liver function tests were carried out which included quantitative serum bilirubin, bromsulphthalein excretion, cephalin cholesterol, thymol turbidity, urine urobilinogen, and urine coproporphyrin. The degree of functional impairment in the five cases studied was slight contrasted with the extensive histologic changes. These observations indicate that hepatic changes may occur more frequently than is generally recognized in patients with active brucellosis.

STUDIES IN CONVALESCENCE FOLLOWING HERNIORRHAPHY: THE EFFECT OF DIET, SUPPLEMENTS, AND AMBULATION ON METABOLIC CHANGES AND ON THE PERFORMANCE OF PATIENTS AS MEASURED BY TESTS OF CARDIOVASCULAR EFFICIENCY AND MUSCULAR FITNESS

R. W. KEETON, M.D., W. H. COLE, M.D., N. O. CALLOWAY, M.D., N. GLICKMAN, M.S., H. H. MITCHELL, PH.D., J. DYNIEWICZ, PH.C., AND D. HOWES, B.S., CHICAGO AND URBANA, ILL.

An attempt was made to determine the extent and duration of convalescence from surgical trauma and to find means of shortening it. The progress of convalescence was measured by a study of certain metabolic factors and performance tests.

The liver was the organ primarily affected in ninety-seven healthy men submitted to herniorrhaphy. The decrement in liver function, as measured by twenty-four hour urobilinogen excretion, bromsulphthalein retention, and other tests, lasted about five days and returned slowly to normal. The decrement was considerably greater in patients who developed complications with infections in chest or wound. The decrement could be prevented by high protein and high caloric feedings, combined with ambulation, systematic exercises, and the administration of certain supplements.

The negative nitrogen balance usually observed postoperatively in patients of the control group on the usual hospital regime was prevented by the same measures which prevented the decrement in liver function. Ambulation alone caused a shift in nitrogen balance toward the positive side.

Attempts to use 17-ketosteroid excretion, creatine excretion, creatinine excretion, renal tests, and many additional liver-function tests were of little clinical value.

The cardiovascular efficiency was measured by the response of the patient on the tilt-table, stair-climbing test, step-up test, and an over-the-bed, push-up test. A single, numerical value has been developed for expressing the cardiovascular response to tilting.

Patients who were on the program of full ambulation exhibited less cardiovascular impairment than those on a program of modified ambulation or those on the control program. Patients who received adequate quantities of proteins and calories throughout the postoperative period (tube fed) also showed less impairment than the controls. This indicates that adequate proteins and calories exerted a favorable effect on circulatory efficiency.

The strength of hand grip, the endurance time of hand grip, and the response to selected psychomotor tests showed no significant decrements.

The expected temperature and pulse rate variations of patients exhibiting normal convalescence will be illustrated and described.

The totality of the results indicates that a herniorrhaphy is a slight operative load. It is a more useful procedure for studying metabolic changes than those revealed by performance tests. It is an excellent experimental procedure, since it is possible to secure adequate controls and the patients can all be brought to a normal state of health prior to operation.

DISCUSSION

DR. RICHARD M. JOHNSON, Long Beach, Calif.—I want to ask what you mean by high caloric intake. There seems to be some doubt if nitrogen balance can be maintained on less than 1,500 calories a day, so I would like to find out how many calories you give. I think that this is an important study, and in any study of this sort it is important to know how much activity the patient has and how much his muscles are used.

DR. M. A. BLANKENHORN, Cincinnati, Ohio.—I would like to ask the essayist if he has compared all wound infections with infections of the lung with atelectasis. I have in mind that a lung infection might result in an anoxia. This might be an important determining factor in the urobilin output. I would also like to ask if these were all urine urobilin determinations and whether any accounting was made of the stool urobilin.

DR. WARREN B. COOKSEY, Detroit, Mich.—Are there any preliminary reports on more prolonged or more chronic illnesses? I did not understand whether these patients were in the younger age group or whether they were an army group. Certainly Dr. Keeton and his co-workers deserve our commendation. I have the feeling that clinically an organized convalescence is of great value, but I know how difficult it is to get any support for a program of this sort. I can testify to this after seventeen years of attempting through subsidy and endowment to create a really good convalescent facility for Detroit, which is, I believe, a typical American city in this respect. We are barely able to keep a thirty-five bed endowed institution full of true convalescents. We are flooded with chronic and senile cases. We must pay more attention to the convalescent problem, and Dr. Keeton's work is an excellent start.

DR. CECIL J. WATSON, Minneapolis, Minn.—I judge that there is less urobilin excreted in patients who have been given spinal anesthesia. What type of inhalation anesthesia was used in the other patients?

DR. KEETON.—I am quite certain that the problem of calories is important. We regard the basal caloric requirement plus 20 per cent as a maintenance or just maintenance diet. As a matter of fact, these patients lost weight on that diet. When we talk about high caloric diets we mean basal plus 100 per cent. If the basal requirements are 1,700 calories and the

patient is fed 3,400, that should be more than sufficient to take care of the increased requirements associated with operation.

As to the age group of these patients, they were very largely young men who were furnished to us through the draft boards. Consequently, we believe that this constitutes a good control group for the study of operations because the subjects were relatively normal. I appreciate the suggestion made that when we start on most operations we are working on sick individuals and it becomes more difficult to study the patient's physiology prior to his operation.

We have not made any careful study of patients' response based on the types of infection. I simply gave you all the infections which arose in the course of this operation. We have recently agreed that in order to standardize further our procedures we would use penicillin as a prophylaxis for postoperative pulmonary infections.

The anesthetic which was used was nitrous oxide induction with ether. Pontocaine was used for the spinal anesthetic. No determinations were made of the urobilinogen in the stools.

RELATION BETWEEN STRUCTURAL AND FUNCTIONAL ALTERATIONS OF THE LIVER

HANS POPPER, M.D. (BY INVITATION), MURRAY FRANKLIN, M.D.
(BY INVITATION), FREDERICK STEIGMANN, M.D., AND
DONALD D. KOZOLL, M.D., CHICAGO, ILL.

In eighty-five patients suffering from various hepatic diseases (infection and toxic hepatitis, cirrhosis, benign and malignant extrahepatic obstruction and other hepatomegalies), liver biopsies were performed by needle; they were repeated in twenty-seven instances, sometimes by surgical excision. Prior to each biopsy several liver function tests were performed. In general, the histologic diagnosis agreed with that derived from clinical and laboratory observations. Occasionally, the histologic differentiation of biliary hepatitis due to extrahepatic obstruction from infectious and particularly toxic hepatitis was difficult. Sometimes the clinical impression was corrected by the histologic findings.

To evaluate morphologically the liver function tests, the degree of each histologically demonstrable change was plotted against the result of each test and statistically evaluated. From the material examined so far, a close correlation appeared between diffuse damage of the epithelial liver cells (characterized by histologic criteria) and pathologic results in cephalin cholesterol flocculation, thymol turbidity, and bromsulfalein tests; between moderate relation to reduction of prothrombin time, increase of serum bilirubin, and reversal of A/ ratio; and between slight relation to increase in sedimentation rate, urinary urobilinogen, N. P. N., and decrease in cholesterol ester ratio and serum vitamin A. No quantitative relation appeared to serum alkaline phosphatase, total cholesterol, fecal urobilinogen, and direct-indirect bilirubin ratio.

In contrast, focal parenchymal necrosis bore a slight relation only to cephalin flocculation, thymol turbidity, and serum vitamin A, indicating that focal damage, even if more severe than diffuse liver cell damage, may escape recognition by function tests. Regeneration of the liver cells showed a significant relationship to thymol turbidity and a questionable one to cephalin flocculation and serum vitamin A. Regeneration was more often found when dro

in cholesterol esters and A/G reversal were moderate than if advanced. Reconstruction of the lobular pattern appeared related to cephalin flocculation, less to thymol turbidity. With marked inflammatory activity in the periportal fields, the sedimentation rate was uniformly elevated; the former bore some relation to cephalin flocculation, increased serum bilirubin, and reduced prothrombin time. Its relation to thymol turbidity and urinary urobilinogen was equivocal. Increased activity of Kupffer cells coincided only somewhat with A/G reversal, reduced cholesterol esters, increased serum bilirubin, and elevated thymol turbidity.

Although obviously marked overlapping occurs between histologic changes in the individual patient, it is nevertheless hoped that this morphologic approach may help in the diagnosis of hepatic disease by establishing relations between results of function tests and the different pathologic phenomena within the liver.

DISCUSSION

DR. CECIL J. WATSON, Minneapolis, Minn.—Dr. Hoffbauer and I often have been impressed with the striking lack of correlation between histologic evidence of disease and changes as reflected by some of the functional tests. This was first borne in upon us several years ago in studying liver damage due to sulfanilamide. In many of these cases we saw outspoken jaundice with other evidence of liver dysfunction but with surprisingly little histologic evidence of impairment. Conversely, we often have seen instances of cirrhosis of the liver in which there was but little evidence of functional impairment in spite of marked histologic derangement.

I should like to emphasize that group of cases of late or chronic hepatitis with jaundice which is perhaps best designated as cholangiolitic hepatitis, in which liver cell function has returned to normal and the appearance of the liver cells as studied by means of biopsy is found to be normal. One often sees little in the biopsies from this sort of case, although the condition is inflammatory. Because of marked evidence of regurgitation of bile in the blood, one can only conclude that there is a functional injury of the cholangiolar epithelium.

I notice that Dr. Popper has used a simple Ehrlich test and I presume that the test was carried out on single samples or short period collections of urine. I think the upper limit of normal which he gives as 3 units is too high. We studied sixty normal students and in that group found that 95 per cent had less than 1 unit in two-hour samples from 2 to 4 in the afternoon; the rest ranged up to 1.5 units. We are inclined to believe that 1.5 units represent the upper limit of normal, although there may be borderline cases up to 2.0 units. We have regarded anything over 2 units as distinctly abnormal.

I should like to emphasize that this procedure has limited value. It has a good deal of value because of its simplicity and the ease with which it can be applied to a large number of individuals. On the other hand, we have seen individuals with liver disease who had a normal value over a short period of time, and yet in the same twenty-four hour period the urobilinogen might show a considerable degree of elevation.

DR. FREDERICK W. HOFFBAUER, Minneapolis, Minn.—I should like to compliment Dr. Popper and his associates on this study. I would like also to ask about the distinction between extrahepatic biliary obstruction and hepatitis on the basis of biopsy. We have thought that if the biopsy could be secured early in the course of the jaundice the distinction would be possible, but when the biopsy is made after the patient has been jaundiced for three or four weeks, the pathologist will have considerable difficulty distinguishing between the changes that occur in extrahepatic obstruction and those that occur in hepatitis.

I should like also to ask about the degree of depression of cholesterol esters in patients with biopsy evidence of fatty livers. I am sure the surgeons would welcome some evidence

that would denote or at least lead them to suspect fatty infiltration of the liver. How extensive were the changes in the cholesterol ester fractions?

DR. LEON SCHUFF, Cincinnati, Ohio.—I would like to ask Dr. Popper if he has noticed any specific changes in the livers of those patients with hepatitis in whom the jaundice appears to be completely obstructive in character. These cases present laboratory changes that cause them to be confused with cases of obstructive jaundice due to stone or tumor. Is there any specific change in the liver biopsy specimens in this particular group of hepatitis often called cholangiolitic form of hepatitis?

DR. POPPER.—First, I want to stress once more that in a certain number of patients examined, discrepancies between anatomical and functional changes were found. For instance, a certain percentage of patients who revealed liver function impairment did not show liver cell damage in the biopsy specimen and vice versa. What we are attempting is a statistical approach comprising all cases.

We can confirm the observations of Dr. Watson as to the occurrence of the morphologic picture of cholangiolitic cirrhosis without significant disturbance of many of the liver functions. We have five cases of this type on record.

As to the question of histologic differentiation between the various types of hepatitis, we found the morphologic differentiation between infectious (viral) hepatitis from toxic hepatitis due to a variety of causes not too difficult to make. We believe we have histologic criteria as well for the fatal as for the nonfatal form of these diseases. On the other hand, the differentiation between toxic hepatitis from biliary hepatitis due to extrahepatic obstruction is sometimes difficult. We have made most of our mistakes in the interpretation of liver biopsies along this line. We are trying, at present, to develop histologic criteria by obtaining additional experience on those cases. One reliable evidence for a biliary hepatitis due to extrahepatic obstruction is the so-called bile infarct which represents necrotic areas impregnated with bile. It does not occur in other groups. We are at a loss to explain the morphologic cause of intrahepatic biliary obstruction and we accept the explanation of Watson and Hoffbauer, namely, that of a morphologically unrecognizable reflux through the bile ducts.

We are encountering difficulties in the chemical determination of cholesterol esters in using the colorimetric method. In our material fatty changes were often accompanied by a decrease in the cholesterol ester percentage. On the other hand, we occasionally saw severe hepatitis with little decrease of the ester percentage.

HEPATITIS WITHOUT JAUNDICE IN INFECTIOUS MONONUCLEOSIS

QUIN B. DEMARSH, M.D. (BY INVITATION), AND HOWARD L. ALT, M.D.,
CHICAGO, ILL.

From reports of punch biopsies, the jaundice occasionally associated with infectious mononucleosis has been shown to be due to parenchymatous changes in the liver not unlike those seen in infectious hepatitis. Similar changes in the liver have been reported in a nonjaundiced case of infectious mononucleosis. Cohn and Lidman (1946) found evidence of impaired liver function in fifteen consecutive cases of infectious mononucleosis without jaundice.

We have performed serial liver function tests in nineteen consecutive cases of infectious mononucleosis without jaundice (icterus indices of 10 units or less). Some degree of hepatic dysfunction was present in all cases as shown by the cephalin-cholesterol flocculation and sulfobromophthalein excretion tests. The maximum dye retention was 36 per cent in one hour. An abnormal albumin-globulin ratio was present in two out of ten cases in which it was determined.

There was a correlation between the severity of symptoms and the degree of liver damage. The usual duration of hepatic dysfunction was three to six weeks, but in three cases it persisted for three to four and one-half months. The liver was palpable and/or tender in eight of the nineteen cases.

The treatment consisted of rest, a high protein, high carbohydrate diet, and vitamin supplements. We have no evidence that the course of the disease was influenced by the diet. Patients who resumed moderate activity before the liver function returned to normal had no relapse of liver disease as indicated by liver function tests or by an increase in size and tenderness of the liver.

DISCUSSION

DR. A. E. FELLER, Cleveland, Ohio.—How was the diagnosis established in these cases?

DR. DeMARSH.—We performed serial white blood cell and differential counts in all of these patients. We made the diagnosis clinically first and confirmed it by heterophil agglutination tests. We did not do the absorption test. The clinical picture in each case was very typical and could not be confused with anything else.

THE EXPERIMENTAL PRODUCTION OF JAUNDICE OF THE DIRECT-REACTING TYPE BY THE INJECTION OF A PREPARATION OF DIRECT-REACTING BILIRUBIN

F. E. SNAPP, M.D. (BY INVITATION), M. GUTMANN, M.S. (BY INVITATION),
T. W. LI, PH.D. (BY INVITATION), AND A. C. IVY, PH.D., CHICAGO, ILL.

By making an alkaline aqueous solution of crystalline bilirubin and mixing it with pooled canine plasma, and then injecting this alkaline bilirubin-plasma mixture into dogs, a direct-reacting type of jaundice, as occurs in obstructive jaundice, can be produced.

The amount of plasma and source of bilirubin is important; the best mixture is made as follows: 300 mg. of crystalline gallstone bilirubin is dissolved in 45 c.c. of N/10 NaOH, and the resulting solution is added to 300 c.c. of pooled reconstituted canine plasma. When this is given slowly intravenously, no reactions or changes in body temperature have been observed in twelve dogs. For some unknown reason about twice as much bile bilirubin as gallstone bilirubin has to be used to give an equivalent blood retention of the bilirubin (thirty-four tests).

By giving an injection of 200 to 300 mg. of bilirubin plasma every third or fourth day, or smaller doses every day, the jaundice was maintained in three dogs for four weeks. The jaundice cleared in five to seven days after ceasing the administration.

When the jaundice was maintained by giving 50 mg. of bilirubin in 50 c.c. of plasma daily, the only change detected was a delay in rose bengal clearance. With larger doses, the rose bengal clearance was decidedly reduced in three dogs, the alkaline phosphatase was slightly increased in one, the sedimentation rate of erythrocytes was markedly increased in two and slightly in the other, and in four weeks a slight anemia occurred. The animals ate well and did not lose weight.

It is suggested that a method is now available for producing a direct-reacting type of jaundice in patients with arthritis by substituting human for canine plasma in the previously mentioned specifications with the idea of ascertaining whether a remission of the disease may be induced.

DISCUSSION

DR. CECIL J. WATSON, Minneapolis, Minn.—If this method were to be applied in a large series of cases it would be interesting to compare the two forms of jaundice which one might expect, that is, that which is produced immediately due to the injection of bilirubin and that which will ensue in some instances about three months later due to transmission of the virus of homologous serum hepatitis.

THE EFFECT OF METHIONINE UPON THE URINARY NITROGEN IN HUMAN BEINGS AT NORMAL AND LOW LEVELS OF PROTEIN INTAKE*

RICHARD M. JOHNSON, M.D., H. J. DEUEL, JR., PH.D. (BY INVITATION),
MARGARET G. MOREHOUSE, PH.D. (BY INVITATION), AND JOHN W. MEHL,
PH.D. (BY INVITATION), LONG BEACH, CALIF.

Methionine offers considerable protection to the livers of experimental animals against hepatotoxic agents and is thought to be of some therapeutic value in the treatment of certain types of liver disease in man. Methionine has been observed to exert a protein-sparing action in the dog, rat, and chick. This study was undertaken to determine the protein-sparing action of methionine in man.

Eight volunteers were placed upon diets containing 2,000 calories and 11.9 and 2.3 Gm. of nitrogen with and without 3 Gm. d-1 methionine for one or more periods of ten days each.

All subjects were constantly observed by four nurses and an attendant who kept daily records of temperature, pulse, respiration, and physical activity and weekly records of body weight, blood pressure, plasma protein concentration, hemoglobin, and red blood cell counts. The daily urinary excretion of nitrogen, creatinine, and sulfate was determined and stools were weighed. The diets were analyzed for their nitrogen content.

Methionine did not significantly alter the urinary nitrogen or creatinine excretion in any subject under these conditions. About 80 per cent of the methionine given were accounted for by increased urinary sulfate excretion and 10 per cent were excreted as methionine in the urine.

Four volunteers from the Department of Biochemistry were given 600 calories or 1,200 calories containing 0.94 Gm. nitrogen. In this group methionine failed to exert a protein-sparing action. Ninety-six per cent of the methionine taken was accounted for by increased sulfate excretion.

Conclusions.—Methionine did not exert a protein-sparing action at 2,000 caloric intake level containing 11.9 and 2.3 Gm. of nitrogen.

Methionine did not exert a protein-sparing action at a 600 or 1,200 caloric level containing 0.94 Gm. nitrogen.

The methionine was metabolized.

*This work was done under a contract between the University of Southern California and the Research and Development Branch, Military Planning Division of the Office of the Quartermaster General, United States Army.

A species difference for minimum requirements of methionine is suggested.

The daily urinary nitrogen excretion was lowest at the 2,000 caloric intake level and greatest at the 600 caloric intake level.

ULCER OF THE LEG DUE TO ARTERIOLOSCLEROSIS AND ISCHEMIA OCCURRING IN THE PRESENCE OF HYPERTENSIVE DISEASE (HYPERTENSIVE-ISCHEMIC ULCERS)

A PRELIMINARY REPORT

EDGAR A. HINES, JR., M.D., AND EUGENE M. FARBER, M.D. (BY INVITATION),
ROCHESTER, MINN.

A small group of patients has been observed who had painful ulcers of the legs which were difficult to heal and which did not fit into any of the usual clinical classifications of ulcers of the leg. The lesions did not have the appearance of typical stasis ulcers but were ischemic and similar to the ulcers which result from spastic or occlusive involvement of the smaller arteries such as occurs in chronic pernio, livedo reticularis, or senile changes in the skin. However, in this particular group of patients none had any of the commonly recognized conditions producing ischemic or stasis ulcers, and no dermatitis was present. The usual diagnosis was ischemic ulcer of undetermined cause.

After observation of several patients it was noted that, aside from the fact that they were all women with the same type of ulcer of the legs, they had one condition in common, namely, hypertensive disease of long duration and considerable sclerosis of the retinal arterioles of the chronic hypertensive type. It was considered that changes similar to those in the retinal arterioles could also occur in the small arteries of the skin and subcutaneous tissues and could give rise to small areas of infarction of the skin. As the result of trauma or for some unknown reason, the skin might break down and such an ischemic ulcer would form.

The first case in which we considered that the ulcer on the leg might be related to vascular changes in the skin due to long-standing hypertensive disease was observed in 1941. Up to the present time we have observed seven patients and have obtained from the file of the clinic records of four patients who had the typical ulcers and hypertensive disease of long duration and no other vascular or cutaneous disease which could account satisfactorily for the lesions. We are presenting this group of eleven cases as a possible new syndrome, with the hope that additional observation and study will further clarify the cause and treatment of these lesions.

Histopathologic study of specimens from the ulcers and of the adjacent skin in five cases revealed organic changes in the arterioles. The most common changes were an increase in the thickness of the arteriolar wall and a decrease in the diameter of the lumen. An increase in the number and size of the nuclei and hyaline degeneration in the media, intimal proliferation, and periarteritis were also noted. The changes paralleled those reported by Keith, Wagener, and Barker from their studies of the pectoralis major muscles in cases of essential hypertension. There were no significant pathologic changes in the sections from the tissue removed from the ulcers except with reference to the arterioles.

Tentative criteria for the diagnosis of hypertensive-ischemic ulcer of the leg should include: (1) hypertension, (2) an ischemic appearing ulcer, (3) indolence of ulcer, (4) moderate to severe pain, (5) poor response to conventional treatment, and (6) typical changes of the blood vessels in and near the lesion as indicated by biopsy. The following should be ruled out before the diagnosis is made: (1) significant chronic venous insufficiency, (2) occlusive arterial disease, (3) syphilis, (4) blood dyscrasia, (5) cutaneous sensitivity to drugs, frostbite, seasonal variations affecting the occurrence of the lesions, or serious local injury, and (6) other diseases on pathologic study of the lesion.

DISCUSSION

DR. ROY W. SCOTT, Cleveland, Ohio.—Will you tell us what therapeutic management you have found of most value in these cases?

DR. A. A. HOLBROOK, MILWAUKEE, WIS.—Several of the photographs of leg lesions looked like cutaneous diphtheria. I wonder if any culture studies were made.

DR. HINES.—In regard to treatment, we have considered these patients from the standpoint of an occlusive arterial disease. Treatment has included such vasodilators as heat or diathermy applied to other parts of the body than the lower extremities, typhoid vaccine administered intravenously to produce fever in the younger patients, and occasionally whisky given orally. I believe this approach has been helpful. Of the various local applications tried, and they have been numerous, it would seem that powdered blood cells worked the best. The ulcers were slow to heal but they did heal eventually.

Cutaneous diphtheria was considered in several cases. Cultures were made several times in each case and we found no special organisms in these cultures. I do not believe the condition can be considered as cutaneous diphtheria.

AORTIC STENOSIS: AN ANALYSIS OF 106 PROVED CASES

CARL KUMPE, M.D. (BY INVITATION), AND WILLIAM B. BEAN, M.D.
CINCINNATI, OHIO

Recently two instances of advanced aortic stenosis with bizarre clinical findings were studied during a single week on the wards of the Cincinnati General Hospital. Because the diagnosis was missed we have undertaken a review of all cases of aortic stenosis without significant lesions of other valves which have come to autopsy in the Department of Pathology in the last twenty-six years. We found 106 cases from a total of 15,806 records. A survey of medical reports and textbook discussions of aortic stenosis revealed great emphasis upon the classical signs of basal systolic murmur transmitted upward, and thrill, but little or no consideration of the atypical case which in our experience has actually predominated. Correct diagnosis, unless established in a former admission, was rarely made in the presence of acute cardiac failure of either forward or backward variety because of the absence of classical signs. The most common mistakes in diagnosis were primary disease of the central nervous system (that is, cerebral vascular accident, epilepsy), acute myocardial infarction, and pulmonary embolism. Even when the diagnosis of aortic stenosis was correct, mitral stenosis was diagnosed frequently but not found post mortem.

The history, mode of onset, electrocardiogram, x-ray, clinical and laboratory data, course of the disease, and manner of death will be correlated with the

cardiac and other findings at autopsy. Although syncopal attacks and even transient hemiparesis were fairly frequent, dizziness and petit mal-like seizures were very common as were anginal pain and paroxysms of dyspnea. A terminal state of shock with symptoms referable to a variety of organs was encountered often. Advanced degrees of aortic stenosis were found to be compatible with a relatively long life, especially if the patient lived within the narrow margins of his cardiac reserve. With these points in mind recent experience has shown that the diagnosis of aortic stenosis can be made without the classical signs if the possibility is kept in mind. In fact the local trend now is in danger of swinging too far.

DISCUSSION

DR. ROY W. SCOTT, Cleveland, Ohio.—The difficulties in making a definite diagnosis in patients with congestive heart failure are well established. We all have missed these patients and have been surprised to find very marked aortic stenosis at the post-mortem table. I hope that Dr. Kumpe will comment on the question of whether calcific aortic stenosis is a distinct entity or whether it is always due, as some believe, to a preceding inflammatory process involving the aortic leaflets.

DR. KUMPE.—In reference to the question about calcific aortic stenosis we do not have any answer. We did not go into the pathology. Dr. Bean agreed that it was a good topic to avoid.

In reference to the question about pure congenital aortic stenosis, no case was considered to be congenital in this series.

As to the electrocardiographic changes, forty-four showed left axis deviation, seven no axis deviation, and one a transient early right axis deviation which later returned to no axis; there were twelve auricular fibrillations, and there was a P-R interval in twenty-one cases over 0.2 second.

AN ANALYSIS OF IMMEDIATE MORTALITY IN 572 CASES OF RECENT MYOCARDIAL INFARCTION

L. N. KATZ, M.D., AND S. S. MINTZ, M.D. (BY INVITATION), CHICAGO, ILL.

A series of 572 cases seen at the Michael Reese Hospital between 1940 and 1945 inclusive have been investigated to determine some of the factors involved in causing immediate mortality (during the hospital stay). Hypertension appears to have no influence on the immediate prognosis of acute myocardial infarction. Diabetes mellitus definitely adds to the gravity of the prognosis, especially in women. It increases the frequency of death by precipitating uncontrolled diabetes and ketosis. Angina pectoris preceding acute infarction has no significant effect on the immediate prognosis. However, the persistence of anginal pain after the attack makes the immediate prognosis graver. Pulse pressures of 25 mm. Hg or less are of great prognostic significance. A systolic blood pressure drop to 90 mm. Hg for several days is a poor prognostic sign. The presence of shock has a similar implication. In the hypertensive group a drop of systolic pressure to 100 mm. Hg for three to five days makes the immediate prognosis poor. The immediate mortality is greater in patients having an infarct involving the septum or one showing atypical or combined patterns. There is no significant difference in the mortality rate of anterior and posterior wall infarcts. In all types the mortality rate is higher in women than in men. Cardiac arrhythmias make the immediate prognosis grave especially when

quinidine and/or digitalis are exhibited. The most serious types of arrhythmias are frequent ventricular premature systoles and intraventricular block. The presence of congestive heart failure is a grave prognostic sign. There is an added hazard in the use of digitalis in such patients, the immediate mortality being higher in those patients who received digitalis. Thromboembolic phenomena occurring during recent myocardial infarction have a grave prognostic significance.

DISCUSSION

DR. ROY W. SCOTT, Cleveland, Ohio.—Do you have any data on the relation between the duration of shock after the initial attack and the ultimate prognosis? It has seemed to me that the longer the patient remained in shock the surer he was to die.

DR. CECIL STRIKER, Cincinnati, Ohio.—I would like to ask if Dr. Katz has any opinion on the use of anticoagulants as a factor against these mortality statistics.

DR. M. J. SHAPIRO, Minneapolis, Minn.—I should like to ask if Dr. Katz concludes that one should not use quinidine at all in the treatment of coronary thrombosis.

DR. MOSES BARRON, Minneapolis, Minn.—I would like to know how many of the patients showed embolic phenomena. I also would like to ask about the use of digitalis in coronary thrombosis, since Dr. Katz spoke of the dangers of its use. It is true that we have to be careful in the use of digitalis in these cases; however, when there is congestive heart failure digitalis should be used but in a smaller dose. Would this method also contribute to the death in such cases?

DR. HENRY T. RICKETTS, Chicago, Ill.—I should like to ask what evidence Dr. Katz has that the administration of insulin, short of producing hypoglycemia, is harmful to the patient with diabetes with myocardial infarction. If he believes that patients with infarction are benefited by hyperglycemia, is it his custom to administer glucose routinely?

DR. JOHNSON MCGUIRE, Cincinnati, Ohio.—How late in the course of convalescence did embolic phenomena occur?

DR. HAROLD C. LUETH, Omaha, Neb.—I would like to ask Dr. Katz if he made a study of the degree of cyanosis and its relationship to mortality in myocardial infarction.

DR. WARREN B. COOKSEY, Detroit, Mich.—I feel that there is indeed an occasional direct relationship between strenuous exercise and coronary thrombosis. Dr. Katz does not state the time element involved in his study. Surgeons know that several days may elapse before signs of thrombus develop after a blood vessel trauma, and this should be borne in mind in relation to coronary thrombosis. A few years ago a study of 100 patients under my care seemed to show that seventeen of them were sedentary individuals who had engaged in strenuous physical exertion within twenty-four to forty-eight hours of their signs of complete occlusion.

DR. ROY W. SCOTT, Cleveland, Ohio.—What about post-mortem evidence of hemorrhage?

DR. CARL F. SHAFFER, Houston, Texas.—What are your criteria for diagnosis?

DR. KATZ.—We have no adequate data on the duration of shock and the ultimate prognosis. I would consider, however, that the prognosis would be worse the longer the duration of shock.

As to anticoagulants, I think that the cooperative study which Dr. Wright has set up may settle this when 1,000 cases are carefully studied. My own feeling is that a patient who has had a thromboembolic phenomenon, after the original infarct, should receive anticoagulants. I might be persuaded to give it in all instances of recent infarction.

We use quinidine when there is an indication for it. Multiple premature systoles or paroxysmal tachycardia is one indication. However, quinidine is a dangerous drug and should be given cautiously in acute infarction.

Of the 572 cases in our series 107 patients died (21.8 per cent) and fifty-two had thromboembolic phenomena; of these twenty-nine died (55.8 per cent). Thromboembolic phenomena occurred in 10 per cent of all patients. Thromboembolic phenomena occurred in 27.1 per cent of the patients who died.

Of course we give digitalis. If there is an indication give it, give it slowly and carefully. We are not sure what the cause of death is in these digitalized patients; nevertheless, there is sufficient hazard connected with its use to avoid giving it to every patient with an infarct, unless the patient shows progressive congestive heart failure.

As regards insulin and glucose, I made the statement about the danger of giving insulin to patients with angina because such patients then do not do so well. In acute emergencies insulin is covered with glucose.

I have no specific data on when emboli occur during convalescence, but I would say it is within two weeks after the infarction.

We did not study virus infection in the lungs.

About physical exercise, I point to the work of Blumgart that infarction was found to ensue after unduly severe exercise in Army personnel. In our series one patient had a similar story. We admit that when we take a history there are omissions, that patients may not remember all the facts, and that the questions may prejudice the patient.

We have made no analysis of subintimal coronary hemorrhage in this series.

The criteria of location of a lateral wall infarction in the electrocardiogram is published in my book on electrocardiography.

The Michael Reese Hospital patient population is about equally divided between the two sexes, and the male dominance in infarction is therefore not dependent upon an unequal sex hospital population.

PRESENT STATUS OF THE THERAPY OF EXPERIMENTAL RENAL HYPERTENSION*

G. E. WAKERLIN, M.D., OLIVER KAMM, PH.D. (BY INVITATION), WAYNE DONALDSON, M.S. (BY INVITATION), W. G. MOSS, M.S. (BY INVITATION), HIROAKI MINATOYA, M.S. (BY INVITATION), TED LEFCO, B.S. (BY INVITATION), AND JOHN MARSHALL, B.A. (BY INVITATION), CHICAGO, ILL., AND DETROIT, MICH.

The Council has asked me to present a brief review of the recent research of our group at the University of Illinois with reference to the present status of the therapy of experimental hypertension produced by constriction of the renal arteries, and as more or less summarized in three abstracts in this year's Proceedings of the Central Society for Clinical Research.

The three therapeutic approaches which have received most attention in recent years have involved the use of naphthoquinones, marine and fish liver oils, and renal extracts. Several groups of investigators have reported the successful therapy of renal hypertensive rats and dogs with various quinones, especially the vitamin K naphthoquinones. There is at least one recent favorable report in the literature on the use of water-soluble vitamin K in essential hypertension. However, we have found no antihypertensive effect in renal hypertensive dogs from either fat-soluble or water-soluble vitamin K. This, of course, does not preclude effectiveness in human essential hypertension, since the question of a common partial pathogenesis of experimental renal hypertension and essential hypertension is still unsettled.

*Aided by grants from the John and Mary R. Markle Foundation and the Graduate School Research Fund of the University of Illinois.

Following earlier clinical reports of the value of vitamin A concentrate obtained from fish liver oils in essential hypertension, we tested a vitamin A concentrate as well as a number of other vitamins in the treatment of experimental renal hypertension. None of these was effective except the vitamin A concentrate. Since then our group has tested three other lots of presumably the same vitamin A concentrate and found only one to be slightly antihypertensive. Of two other vitamin A concentrates tested, one showed slight antihypertensive activity. Eleven marine and fish liver oil fractions have proved to have no antihypertensive effect. Another research group has likewise found fish liver and marine oils inconstantly to contain variable amounts of an orally effective antihypertensive principle. This principle is definitely not vitamin A. Assay of its value in human hypertension should await further work on the separation, purification, and, if possible, identification of the principle and its production in adequate quantities.

A number of workers have reported the presence of an antihypertensive principle in kidney, but to date no one has produced a consistently effective, reasonably purified preparation properly suited for decisive trial in essential hypertension or human renal hypertension. Our research group has found a crude renal extract to be highly effective in the treatment of renal hypertensive dogs. At first we suggested that the antihypertensive effect was due to the *in vivo* neutralization of renin by antirenin produced as a result of the injections of renin contained in the crude extract, but more recent work makes the antirenin hypothesis very doubtful. Since we have obtained evidence that the antihypertensive activity may be in the nonrenin portion of the crude extract, we have studied about thirty fractions of the crude renal extract, some containing little or no renin. Certain of these fractions have proved to be inconstantly active, but we have not as yet been able to produce a consistently active purified preparation. On the basis of our work to date, we have demonstrated the following properties for the antihypertensive renal principle: (1) water-soluble (at least between pH 4.0 to 8.0); (2) retains at least partial potency for one year at pH 4.0 and 4° C.; (3) fairly resistant to slow freezing; (4) partially stable at 70° C. for twenty minutes; (5) poorly resistant to 40° C. for four hours under vacuum at pH 4.0; (6) probably nondialyzable; (7) partially precipitated by $\frac{1}{12}$ saturation with $(\text{NH}_4)_2\text{SO}_4$; (8) possibly a protein somewhat smaller in size than the pseudoglobulin renin.

We have likewise been able to substantiate our earlier observations that certain renal extracts given prophylactically will prevent the development of experimental renal hypertension in dogs. The technique of renal artery constriction which we have used gives a somewhat higher percentage of hypertension success than that reported by other research groups or obtained by us with slight modifications of the technique.

Recently we have been able to remove renin from the kidney biologically and are in the process of testing nonrenin kidney extract for the antihypertensive renal principle therapeutically and prophylactically. More work is obviously necessary before a sufficiently pure and potent preparation of the antihypertensive renal principle is available for trial in human hypertension.

DISCUSSION

QUESTION.—What about the fever-producing qualities of these kidney extracts?

DR. WAKERLIN.—We studied this and have found that our renal extracts (which are administered intramuscularly) have no pyrogenic effect.

THE RESULTS OF SURGERY IN PATENT DUCTUS ARTERIOSUS

M. J. SHAPIRO, M.D., MINNEAPOLIS, MINN.

This study was done to determine the effectiveness of surgery in patent ductus arteriosus. An analysis has been made of 643 patients who have been operated upon throughout the world. The differences in results of ligation of the duct as compared to section are determined.

Our figures show that at least 10 per cent of the cases that have been ligated have recanalized. It is also indicated that complications are more common with ligation than with section. The over-all picture is exceedingly good. The total mortality rate is approximately 5 per cent.

An analysis of our own sixty-five cases reveals that we have had the average number of recanalizations in those cases that were ligated. In approximately forty consecutive cases in our group where section has been done, there have been no fatalities. Gross, Wangenstein, and Craaford have done 172 sections of the duct with no fatalities. The follow-up study of the majority of these patients reveals the results as excellent.

It is our conclusion that surgery for patent ductus arteriosus is very effective and that the mortality rate has now been reduced to the point where all children with this lesion should be operated upon whether or not they show any evidence of cardiac strain. Surgery being more hazardous in adults, operation should be done only if such patients reveal evidence of cardiac strain, particularly if this is progressive. Patients with subacute bacterial endarteritis should be operated upon as soon as the diagnosis is made, in most instances, without attempting cure of the infection with chemotherapy. As a result of our study, we are convinced that ligation is ineffective and should be replaced by section of the duct, except in rare instances where section is not feasible.

DISCUSSION

DR. EDWARD MASSIE, St. Louis, Mo.—I would like to ask Dr. Shapiro if he would operate upon a patient with patent ductus arteriosus if another lesion were present. We see that condition frequently and a decision has to be made as to what should be done. I sometimes hesitate in view of the presence of the other lesion.

DR. SHAPIRO.—We had one patient operated upon who had both a patent ductus and an interventricular septal defect. We predicted that the machinery murmur would disappear but that the murmur at the lower end of the sternum would persist after surgery, and this is what happened. It was important in this instance to be aware of both lesions, as it might be concluded that surgery had failed because a murmur in the heart was still present. We have another such case scheduled for surgery. This patient has a patent ductus, an interventricular septal defect, and a complete heart block undoubtedly on the basis of the defective septum. There is every reason why the patent ductus should be closed in such cases.

The question of differential diagnosis between patent ductus arteriosus and interventricular septal defect is not difficult to answer. It must be realized that patency of the duct is an

extracardiac lesion while the interauricular septal defect is intracardiac. A patent duct of any appreciable size is always accompanied by peripheral vascular changes secondary to a wide pulse pressure while an interauricular septal defect of any size produces no change in the peripheral vascular system.

PULMONARY ARTERIOVENOUS FISTULA WITH SECONDARY POLYCYTHEMIA OCCURRING IN TWO BROTHERS: CURE BY PNEUMONECTOMY

ALFRED GOLDMAN, M.D., ST. LOUIS, MO.

This report is based on two cases of pulmonary arteriovenous fistula producing secondary polycythemia, occurring in brothers.

The first case is that of a 22-year-old man who had a long-standing polycythemia ranging up to 11,000,000 red blood cells, cyanosis, and clubbing of the extremities, all of which were known to be present since early childhood. An x-ray of the chest showed a mass in the left hilum and left mid-lung field which on fluoroscopic examination showed pulsation. There was no evidence of heart disease. The diagnosis of a cavernous angioma acting as a pulmonary arteriovenous fistula was made. A left pneumonectomy was recently performed. The lung showed a series of widely communicating channels between the pulmonary arteries and the veins, so that a good portion of the blood entering into the left lung poured directly into the pulmonary veins without oxygenation. Following the operation there was a rapid disappearance of the cyanosis, polycythemia, and clubbing of the extremities.

The second case is that of the 32-year-old brother. The red blood count was 7,000,000. There was a marked cyanosis and slight clubbing of the fingers. An x-ray of the chest showed a mass in the left mid-lung field which had a definite pulsation on fluoroscopic examination.

These two cases are the fourth and tenth cases, respectively, of pulmonary arteriovenous fistula with secondary polycythemia to be reported. This is the first time that the disease has been reported in two members of one family. A study of all ten cases shows such a characteristic and uniform picture that a clinical syndrome due to a large arteriovenous fistula can be established. A combination of polycythemia, clubbing of the extremities, a low arterial oxygen saturation, negative cardiac findings, plus an unexplained chronic pulsating pulmonary lesion is pathognomonic of a pulmonary arteriovenous fistula. Surgical removal of the lesion results in a clinical cure.

DISCUSSION

DR. EMMET BAY, Chicago, Ill.—There was no demonstrable right heart enlargement in the first case. The large pulmonary arteriovenous fistula was shown in the pathologic specimen and I cannot figure out the mechanics of this situation. I would think the output from the right heart would have to be increased with each heartbeat.

DR. MILTON LANDOWNE, Chicago, Ill.—I should like to bring up the following two points:

(1) The tests which are used to support the diagnosis of a right to left shunt in congenital heart disease would also be expected to reveal the presence of a pulmonary arteriovenous fistula. Thus, one would expect peripheral manifestations of intravenously injected

ether (as described for congenital heart disease by Benenson and Hitzig) and possibly an apparent reduction in the "arm to tongue" depending on the size of the shunt and the amount of material used for the test.

(2) Adams, Thornton, and Eichelberger recently have reported upon the successful surgical treatment of this condition. In their case a familial nature of the disease was also suggested. They found a suggestive pulmonary shadow in the x-ray of the patient's father and in addition, their patient, his father, and possibly several other members of the family had bleeding telangiectases of the nose and mouth. I wonder whether these cases may not ultimately be classified, therefore, as a variety of Osler's familial hemorrhagic telangiectasia.

DR. GOLDMAN.—One would expect to find enlargement of the right heart as the result of a pulmonary arteriovenous fistula. However, it did not occur; this is in contrast to the situation in peripheral arteriovenous fistulas. There has been no case report in which there are any changes in the heart as a result of the fistula. This is explained by the fact that the lesion involves only the pulmonary circulation. None of the three cases that came to post mortem showed any cardiac changes attributable to the arteriovenous aneurysm.

THE DIAGNOSTIC VALUE OF ELECTROCARDIOGRAPHIC PATTERNS BASED ON AN ASSAY OF 261 ADDITIONAL AUTOPSIED CASES

L. N. KATZ, M.D., D. FELDMAN, M.D. (BY INVITATION), AND
R. LANGENDORF, M.D., CHICAGO, ILL.

An analysis was made of a consecutive series of 261 cases necropsied within two months after they had had an electrocardiogram made. The purpose of this study was to determine the accuracy and dependability of our electrocardiographic criteria. The thirteen specific patterns encountered are enumerated and the criteria listed. In this series forty-one cases were encountered in which discrepancy existed between the necropsy findings and the electrocardiogram; in the other 220 cases (84.3 per cent) no discrepancy was found. In general the electrocardiogram is a good index of anatomic normality and abnormality of the heart, although its use is limited by its inability to distinguish in many cases between the clinical and subclinical forms of heart disease. An abnormal electrocardiogram is excellent evidence for anatomic abnormality. A normal electrocardiogram, however, is occasionally found with an abnormal heart.

Ventricular hypertrophy is usually reflected in the electrocardiogram by heart strain patterns. Left ventricular hypertrophy more often gives rise to its strain pattern than right ventricular hypertrophy. With combined ventricular hypertrophy the pattern seen is of the predominantly hypertrophic ventricle more often than a pattern diagnostic of combined heart strain.

Recent myocardial infarctions, especially if serial records are available, are seldom missed electrocardiographically. However, old infarcts or severe coronary sclerosis without confluent infarction sometimes give rise to patterns resembling those of recent infarction. Old healed myocardial infarctions can often be diagnosed electrocardiographically but not with the regularity of recent infarction. Coronary sclerosis without myocardial infarction generally results in nonspecific electrocardiographic abnormalities.

This study confirms our previous one, making a total of 410 consecutive cases analyzed. The value of specific patterns in electrocardiography, when properly used, is thus established.

ANTITULARENSE SERUM: CORRELATION BETWEEN PROTECTIVE CAPACITY FOR WHITE RATS AND PRECIPITABLE ANTIBODY CONTENT

LEE FOSHAY, M.D., I. RUCHMAN, PH.D. (BY INVITATION), AND
P. S. NICHOLAS, PH.D. (BY INVITATION), CINCINNATI, OHIO

Antitularense sera have hitherto failed to reveal protective antibody against challenge with strains of maximal virulence whenever the test animals were the mouse, guinea pig, hamster, or rabbit. Past inability to protect highly susceptible animals has encouraged an unfounded belief that serum therapy is therefore ineffective in the human disease. Since the reaction to tularemia infection by the rat approximates more closely that of man than do those of other animals, the rat was used for serum protection experiments.

Protective antibody was readily demonstrated in 2 c.c. quantities of each of four antitularense sera by intraperitoneal injection of the 85 to 110 gram white rat and by immediate subcutaneous challenge with 25 million viable organisms of maximal virulence, an average of 25,000 LD₅₀ rat doses.

Precipitable antibody content of sera was quantitated by the Culbertson neutralization method, using a polysaccharide prepared from acetone-extracted cells of a virulent strain by the phenol extraction method of Palmer and Gerlough.

Rat mortality was the criterion by which serum protection was judged.

Prechallenge treatment with normal sera gave 95 per cent mortality. Pre-treatment with the most potent hyperimmune serum, aged fifteen months, gave 12.5 per cent mortality. Sera of lesser potency gave correspondingly greater mortality. Mortality rates were roughly inversely proportional to precipitable antibody contents of sera. There was good agreement between antibody content and protective capacity for four immune sera of graded potencies.

The difference in clinical effectiveness between the two best sera was of the order of that shown by both rat protection and antibody content tests.

INFLUENZA B: STUDY OF A LOCALIZED OUTBREAK PRECEDING THE 1945 EPIDEMIC*

A. E. FELLER, M.D., CLEVELAND, OHIO

The present report is concerned with a clinical and serologic study of a localized outbreak of influenza B, which occurred in a battery of 230 recruits during the summer of 1945 at Fort Bragg, N. C. The battery had been under observation previous to the outbreak and was studied for a total period of approximately four months. Blood specimens were obtained at the beginning and end of the period of observation, thus providing the basis for correlating the clinical studies with the serologic findings.

The data showed that "recognized" and "inapparent" infections occurred with approximately equal frequency. The "recognized" infections occurred principally during a period of three weeks, indicating that a definite outbreak had occurred. However, more than half of the total infections were concentrated

*From the Commission on Acute Respiratory Diseases.

in only one of the four platoons comprising the battery. Thus, the outbreak was localized to one segment of the population, and only sporadic infections occurred in the remainder. There was a direct but not complete relationship between low antibody titers of the initial sera and subsequent large increases in titer to influenza virus B. Also, the initial sera from those individuals who subsequently developed a febrile respiratory illness tended to have lower titers than did the sera from individuals who had either an afebrile respiratory illness or no recognized illness.

The localized nature of the outbreak seems to have been characteristic of the manner in which influenza B occurred in other parts of the country during the period of several months preceding the widespread epidemic of influenza B in the fall and winter of 1945. The fact that influenza A also occurred in a similar manner during a period of several months preceding the 1943 epidemic suggests that the sporadic or localized occurrence of influenza may indicate the imminence of an epidemic. Furthermore, the correlations between initial antibody titers and the subsequent development of serologic or clinical evidence of infection indicated that these immunologic aspects of influenza B are similar to those of influenza A.

EVALUATION OF THE TREATMENT OF PRIMARY PNEUMOCOCCIC PNEUMONIA

ROBERT T. THOMPSON, M.D. (BY INVITATION), AND
M. A. BLANKENHORN, M.D., CINCINNATI, OHIO

The degree to which penicillin should supplement sulfonamide drugs in the treatment of pneumococcic pneumonia is a question at the present time. Rather diverse results have been reported from various clinics so that evaluation of results is difficult. One reputable 1945 publication gives two consecutive abstracts on the treatment of pneumococcic pneumonia in which fatality rates are 18.5 and 1.1 per cent, respectively. The treatment of 189 cases of primary pneumococcic pneumonia is evaluated here in an effort to resolve apparent discrepancies in the comparison of other reports.

All of these patients were treated with sulfamerazine. A few received anti-pneumococcic serum, and a few of the later patients were given penicillin after complication developed.

Of the 189 patients treated twenty-six died. Of the 122 patients over 40 years of age twenty-four died. Of twenty-eight patients with bacteremia fourteen died. Type VII pneumococcic pneumonia occurred in thirty-five patients, and eight of these died. Of eight patients who had type VII pneumococcus bacteremia seven died.

Elevation of the blood urea nitrogen above 40 mg. per cent was found in thirty-three of the 189 patients treated. Of these thirty-three patients fourteen recovered and nineteen died.

Nineteen of the twenty-six fatal cases had azotemia prior to death. In fourteen of these it was as great, or greater, before sulfamerazine was started than at any subsequent time. Three others had azotemia before treatment which increased progressively until death. Another had mild azotemia while in shock

prior to death, and the last had a necrotizing angitis due to sulfonamide hypersensitivity which involved the kidneys, heart, liver, and spleen.

Eleven of the sixteen autopsied cases showed pathologic abnormality of the kidneys. One had hypersensitivity angitis of kidneys, two had toxic nephrosis, and eight had chronic disease of the kidneys.

Review of the fatal cases showed that shock, cardiac arrhythmia, and pulmonary edema were notable in the death of pneumococcal pneumonia patients. Every one of the sixteen autopsied cases showed pathologic abnormality of the heart; in one there was thrombotic nonbacterial endocarditis; in four there were changes of an acute toxic nature; and in eleven there were chronic or degenerative changes.

Seven patients who died were treated less than twenty-four hours.

It is concluded that delay in treatment and aggravation of latent disorder often defeat specific treatment for pneumococcal pneumonia.

DISCUSSION

DR. A. E. FELLER, Cleveland, Ohio.—It has been shown that pneumococcal pneumonia can be prevented, but the statement has been made that we now have such good results with sulfonamides and penicillin that it is not worth while to immunize people against this type of pneumonia. It is true that pneumococcal pneumonia does not have a high death rate or high incidence rate in certain age groups, but it seems to me that it would still be worth while to immunize against it because in many circumstances people still die from pneumococcal pneumonia as this study so clearly emphasizes.

A STUDY OF THE ACTION OF BETA-DIMETHYLAMINOETHYL BENZHYDRYL ETHER HYDROCHLORIDE (BENADRYL) IN THE SKIN OF HUMAN BEINGS

MILO D. LEAVITT, JR., M.D. (BY INVITATION), AND CHARLES F. CODE, M.D.,
ROCHESTER, MINN.

A study has been made of the mode of action, in the skin, of beta-dimethylaminoethyl benzhydryl ether hydrochloride (benadryl), a new synthetic antihistamine compound. The experiments were performed on the skin of thirty-three healthy, nonallergic persons; the size of histamine flares resulting from the standard intracutaneous injection of 1 microgram of histamine base was utilized as an indicator of the effectiveness of benadryl as an antihistamine agent. From photographic records made during each procedure, the areas of flares were accurately determined by the use of a planimeter.

Control studies performed on each person revealed that maximal flaring caused by histamine injected into skin infiltrated with isotonic solution of sodium chloride occurred during the first fifteen minutes in 90 to 95 per cent of the persons. During this time interval the maximal size of the flare in forty experiments varied from 16.1 to 24.7 square centimeters.

Histamine flares superimposed on skin infiltrated with benadryl diluted 1:1,000 were reduced 61.6 per cent in size, as compared with control flares. The intravenous administration of 150 mg. of benadryl to ten persons resulted in a 51.7 per cent reduction in size of the flare. The oral administration of 150 mg. of benadryl reduced the size of the flare only 33 per cent.

Benadryl was found to produce local anesthesia when it was injected into skin. Bio-assay, by means of electric algometric determinations, showed that benadryl in dilutions of 1:500, 1:1,000, 1:5,000, 1:10,000, and 1:20,000 possesses anesthetic potency similar to that of dilutions of procaine hydrochloride of 0.5, 0.25, 0.125, 0.0625, and 0.03125 per cent, respectively. Equivalent anesthetic doses of benadryl and procaine hydrochloride exerted definite, but not equal, antihistamine action. Procaine hydrochloride in dilutions of 0.0625 and 0.03125 per cent reduced the size of flares only 23.6 and 23.3 per cent, respectively, whereas benadryl of equal anesthetic potency, 1:10,000 and 1:20,000, caused an 80 per cent reduction in the size of histamine flares.

It was found that the pronounced antihistamine activity of benadryl is not dependent on its anesthetic potency. This was demonstrated in experiments in which injections of histamine were delayed until the anesthetic effects of benadryl and procaine hydrochloride had subsided. Flares developing in sites in which procaine hydrochloride was no longer exerting its anesthetic effect closely approximated the size of control flares. Benadryl, however, in all dilutions reduced the size of flares from 86 to 91 per cent, despite the disappearance of its anesthetic effect.

DISCUSSION

QUESTION.—Have you had any experience with pyribenzamine?

DR. LEAVITT.—Our preliminary experience would lead us to believe its local skin effects are very similar.

DR. CODE.—Unfortunately, even though benadryl is so potent a local anesthetic, it has irritant qualities. Other local anesthetic agents may possess antihistamine properties. State and Wangenstein used procaine in the treatment of delayed serum sickness (*J. A. M. A.* 130: 990-995, April, 1946). It is to be hoped that continued work with these and other antihistamine drugs will aid in solving some of the perplexing problems pertaining to histamine metabolism.

THE OCCURRENCE OF COMBINED SYSTEM DISEASE IN PERSONS WITH PERNICIOUS ANEMIA DURING TREATMENT WITH THE LACTOBACILLUS CASEI FACTOR (FOLIC ACID)

C. F. VILTER, M.D. (BY INVITATION), CINCINNATI, OHIO, R. W. VILTER, M.D., CINCINNATI, OHIO, AND T. D. SPIES, M.D., BIRMINGHAM, ALA.

Remissions in the macrocytic anemia of pernicious anemia, sprue, and pregnancy have been produced repeatedly with the *Lactobacillus casei* factor. This study was undertaken in November, 1945, to answer the following questions: (1) Will *L. casei* factor control the anemia of pernicious anemia and sprue for long periods of time as successfully as liver extract? (2) Will *L. casei* factor therapy prevent the development of the neurologic manifestations of pernicious anemia or control them after they have appeared? This paper presents a progress report at the end of the first year of the study.

The twenty-six subjects of the investigation were patients from the medical wards and dispensary of the Cincinnati General Hospital, twenty-one of whom had pernicious anemia which had been controlled for two to seventeen years by injections of liver extract. Three had pernicious anemia in relapse, and two had sprue which had been poorly controlled by liver extract. Each of these subjects

was treated with 70 to 105 mg. *L. casei* factor per week in divided doses given orally for ten to twelve months. All liver therapy was discontinued. Complete physical and neurologic examinations, erythrocyte counts, hemoglobin levels, hematocrit determinations, and reticulocyte counts were performed at the beginning of the study and were repeated as often as the condition of the patient demanded.

Most of the patients noted an increase in appetite and weight during the year. In only two instances were there moderate decreases in the hematologic values; these occurred after five to eight months while the subjects were receiving the same amount of *L. casei* factor which in each instance had produced a satisfactory remission previously. All manifestations of sprue were well controlled.

After five to eight months parasthesias in the extremities and an unsteady gait developed in four subjects with pernicious anemia. Two of these four subjects are mentioned previously as having developed moderate reductions in hematologic values. Neurologic signs gradually appeared and increased in numbers until there was unequivocal evidence of combined system disease. At this point each of these four patients received 50 to 500 mg. *L. casei* factor daily by mouth for ten to forty days without subjective or objective improvement. Refined liver extract, 5 c.c. intramuscularly daily, was begun after it was obvious that neurologic improvements would not occur or when progression of the disease was so rapid as to endanger the patient's future well-being. Within ten days thereafter subjective and objective neurologic improvement occurred and convalescence is progressing satisfactorily.

The conclusions are drawn that oral *L. casei* factor, 70 to 105 mg. in divided doses per week, will usually maintain patients with pernicious anemia and sprue in a normal hematologic state for a year but will not prevent the occurrence of degenerative disease of the spinal cord and peripheral nerves in patients with pernicious anemia.

NONUTILIZATION OF CONJUGATED FOLIC ACID IN PERNICIOUS ANEMIA

ROBERT W. HEINLE, M.D., EVELYN M. NELSON, B.S. (BY INVITATION),
H. VICTOR NELSON, B.S. (BY INVITATION), AND ARNOLD D. WELCH,
PH. D., M.D. (BY INVITATION), CLEVELAND, OHIO

The response of pernicious and allied macrocytic anemias to folic (pteroyl-glutamic) acid implies that a vitamin deficiency is corrected by this therapy. Of the folic acid occurring in foods, a large proportion consists of conjugates of higher molecular weight; thus, the conjugate of yeast (heptaglutamate) contains six additional glutamic acid molecules. Most mammalian tissues contain enzymes and conjugases that convert heptaglutamate to folic acid, and various animal species effectively utilize this conjugate in lieu of folic acid. Parenteral administration of heptaglutamate to normal man markedly augments the urinary excretion of the free vitamin.

In three patients with pernicious anemia studied, no hematologic response followed either oral or parenteral administration of the conjugate, but a definite response occurred in two of these to whom an equivalent amount of folic acid

was given subsequently. Furthermore, in contrast to the finding in normal man, administration of heptaglutamate to the three patients studied caused little or no augmentation of the urinary elimination of folic acid. Bethell and associates have independently observed the ineffectiveness of heptaglutamate in several patients with pernicious anemia.

Although these findings may offer a basis for the apparent folic acid deficiency of pernicious anemia, a conclusion that the utilization of heptaglutamate is due to a direct action of the antipernicious anemia factor is at present unjustified. Augmentation of the conjugase activity of human bone marrow *in vitro* has appeared to result from the addition of highly purified liver extract, but the results are obtained inconsistently and are of uncertain significance. Conceivably, liver extracts contain a factor necessary for the proper functioning of a conjugase system or a substance concerned with the removal of an inhibitor of a conjugase system. However, the ineffective utilization of the naturally occurring conjugate by patients with pernicious anemia may be secondary to a more deep-seated biochemical derangement.

In favor of this view is the observation that the activity, in patients with pernicious anemia of those conjugase systems studied, is not significantly less than that of normal subjects. Also, the striking effectiveness of purified liver extract in one patient in whom folic acid was almost ineffective, in intramuscular doses up to 12 mg. daily, suggests that the factor(s) of purified liver extracts, although apparently concerned in some way with the release of folic acid from its conjugate, in addition has other functions.

FURTHER STUDIES ON THE UTILIZATION OF PTEROYL HEXA- GLUTAMYL GLUTAMIC ACID (VITAMIN B_c CONJUGATE) IN PERNICIOUS ANEMIA

FRANK H. BETHELL, M.D., ANN ARBOR, MICH., MARION E. SWENDSEID, PH.D.
(BY INVITATION), ORSON D. BIRD, PH.D. (BY INVITATION), AND RAYMOND A.
BROWN, PH.D. (BY INVITATION), DETROIT, MICH., MURIEL C. MEYERS,
M.D., AND GOULD A. ANDREWS, M.D., ANN ARBOR, MICH.

The effectiveness of pteroylglutamic acid* (P. G. A.) in the treatment of certain macrocytic anemias raises the question of the cause of a deficiency of this substance in such anemias. Although widely distributed in common foods, this component of the vitamin B complex is usually present as a conjugate, pteroyl hexaglutamyl glutamic acid. Consequently an apparent deficiency of P. G. A. in persons whose diets have not been grossly inadequate suggests a metabolic defect in the utilization of the natural material. Evidence has been obtained of such a defect by observations of hematologic responses and by determinations of the urinary excretion of P. G. A. in patients with anemia after the oral administration of the vitamin in the conjugated and in the free form. In this communication the results of earlier studies as well as additional investigations on this problem will be reported.

The hexaglutamyl conjugate was given orally in the form of a yeast concentrate to fourteen patients and to six healthy subjects. There were nine

*This is the chemical name of the vitamin which has been referred to as folic acid, vitamin M, or vitamin B_c.

patients with pernicious anemia in relapse, three with pernicious anemia in liver extract induced remission, and two with macrocytic anemia following total or subtotal gastrectomy. Doses of conjugate supplying the equivalent of 4 to 5 mg. of crystalline P. G. A. daily were without effect on the erythrocytes, reticulocytes, hemoglobin, or hematocrit values of any of the patients with anemia. The administration of equal amounts of the vitamin in the free form (Folvite*) was followed in all instances by significant hematologic increases, usually approximating the expected results from adequate oral liver extract or stomach therapy.

The P. G. A. content of the urine was determined by microbiologic assay. No evidence for the excretion of the vitamin as conjugate was obtained in any of the experiments. The excretion of the vitamin while the subjects received unsupplemented diets was generally lower in the case of the patients with macrocytic anemia than in the case of the normal persons.

After the administration of the vitamin conjugate the patients with macrocytic anemia showed no significant increase in excretion of P. G. A., with the exception of one subject who excreted slightly greater amounts, whereas the normal individuals excreted relatively large quantities. After the administration of free vitamin the patients excreted variable amounts, whereas the values for the normal subjects were considerably higher and more constant.

Administration of conjugate to three patients with pernicious anemia who had been receiving parenteral liver extract for a number of years and whose blood values were within normal limits was followed by excretion of the free vitamin in amounts comparable to those excreted by normal persons.

It is believed that these results demonstrate that the normal person can convert the vitamin conjugate to the free form and that in untreated pernicious anemia this ability may be either greatly reduced or entirely lacking.

It seems probable that for P. G. A. to participate in hematopoiesis (megalo-blastic maturation) the vitamin must be present in the free state.

The difference in excretion levels of the vitamin after administration of the conjugate, between patients in relapse and those in liver extract-induced remission, suggests that the principle of liver active in pernicious anemia may be concerned with the conversion of the conjugated vitamin to the free form.

DISCUSSION

DR. BYRON E. HALL, Rochester, Minn.—During the past year observations similar to those just reported by Dr. Vilter and his associates have been made at the Mayo Clinic; namely, that administration of synthetic folic acid neither protects the patient with pernicious anemia from neurologic manifestations nor relieves him of them once they have developed. In our series of fourteen patients with pernicious anemia who were treated for many months by administration of synthetic folic acid, ten instances of peripheral neuropathy as manifested by paresthesia and two of early subacute combined degeneration of the spinal cord were observed before institution of treatment. Of the ten instances of paresthesia improvement occurred in four, temporary improvement followed by relapse occurred in four, and no improvement was observed in two. In the two instances of subacute combined degeneration of the spinal cord which were observed before institution of treatment, evidence of progression of the neurologic manifestations of the disease was noted during administration of synthetic folic acid. In the cases in which symptoms or signs of neurologic involvement did not exist prior to the institution of treatment with folic acid, two instances of paresthesia and three of early

*Lederle Laboratories, Inc., Pearl River, N. Y.

signs of combined sclerosis occurred while treatment was being given. Neurologic manifestations developed in some cases despite induction of satisfactory hematologic remissions.

Another observation has been that of the wide variation in rapidity of hematologic response of patients with pernicious anemia in relapse who were treated with synthetic folic acid. While an occasional patient responds as rapidly to treatment with folic acid as to treatment with liver, the majority respond hematologically more slowly to treatment with folic acid. The response of three of fourteen patients treated with folic acid was very slow and hematologic remissions could not be induced despite administration of fairly large doses of the preparation; however, satisfactory hematologic remissions were induced in all three patients by means of intensive treatment with liver.

The appearance of sternal marrow obtained by serial aspiration in our group of cases has indicated that synthetic folic acid rapidly converts erythropoiesis from a megaloblastic to a normoblastic type. While the effect of this agent on the bone marrow and blood of patients with pernicious anemia in relapse is of great interest, it is obvious that the substitution of synthetic folic acid for liver in treatment of pernicious anemia is extremely hazardous in view of the demonstration that administration of folic acid does not prevent development of neurologic manifestations of the disease.

DR. WALTER L. PALMER, CHICAGO, ILL.—The first two papers and the discussion by Dr. Hall all suggest that folic acid is not a complete substitute for liver extract. It may well be that this is true, but we should be very careful in arriving at this conclusion. I am reminded of the experience we all have had with liver through the years. At first we thought it was not satisfactory in all cases; then we thought the crude form was better than the refined; and finally we decided that refined liver extract was a complete substitute for whole liver and for the crude extract as well. The problem seemed to resolve itself into (1) the method of administration and (2) the dosage. In the first paper the route of administration of the folic acid was oral. We all know that the oral method of administration of liver extract is very unsatisfactory in many instances and that there are some patients who cannot be maintained with normal blood pictures in this manner. With regard to dosage, apparently the largest amount of folic acid given intramuscularly was 12 milligrams. This may not be enough. Would it not be worth while to try 50 mg. per day intramuscularly?

DR. CECIL J. WATSON, Minneapolis, Minn.—I want to ask whether in the urinary excretion studies the results were based on bio-assay technique and whether any studies on conjugated or free folic acid have been made on the feces of these patients.

DR. HOWARD L. ALT, Chicago, Ill.—I would like to ask about the diet these patients received who had relapses of cord disease on folic acid treatment.

DR. M. W. COMFORT, Rochester, Minn.—It might be worth while at this time to mention the disappointing results obtained so far in the treatment of nontropical sprue with synthetic folic acid. This is in contrast to the excellent response of tropical sprue to treatment with the same preparation. My colleagues and I have treated a number of patients who have nontropical sprue with adequate doses of synthetic folic acid for several months. Four patients received 50 to 200 mg. of folic acid a day intramuscularly, and the results to date are as follows: Diarrhea has not been significantly affected and relapses have continued to occur with about the same degree of frequency. In one patient in whom megaloblastic bone marrow was present the bone marrow changed rapidly to a normoblastic type. In all four patients the reticulocytes have responded slightly, but so far the percentage has not exceeded 4. In none of these patients has the size of the erythrocytes been reduced or has the anemia improved to a satisfactory degree. One patient is dead apparently as the result of an exacerbation of the disease, and two are in exceedingly serious condition. Of the patients given folic acid by mouth, changes have not been seen in their condition that could not be ascribed to the fluctuations in the severity of the disease. These disappointing results suggest that in some patients nontropical sprue will not respond favorably to treatment with synthetic folic acid.

DR. R. W. VILTER, Cincinnati, Ohio.—Regarding Dr. Palmer's comments, in working up this paper for presentation I went back over the experiences from 1929 to 1935 with liver extract in this same type of patient. There was considerable divergence of opinion, as

Dr. Palmer indicated, as to the effectiveness of liver extract in combined system disease of pernicious anemia. From the literature I was unable to tell why there was this divergence of opinion because most of the liver extract was given intramuscularly in adequate doses, so I could not come up with any analogy between their experience at that time and our experience now with folic acid. Generally speaking folic acid given by mouth is almost as effectively absorbed and utilized as folic acid given intramuscularly. The average effective dose is usually 2 to 5 mg. by the parenteral route or 10 to 15 mg. by oral route. In contrast, liver extract is poorly absorbed and utilized by the oral route, the effective oral dose being many hundred times the intramuscular dose. The interesting thing regarding the diets of the patients who relapsed is that patients whom we knew were on deficient diets did not develop neurologic symptoms, whereas patients in the private group who were referred because of sensitivity to liver developed neurologic manifestations. The diets of the patients in the private group were much better than those of the patients from the dispensary. I do not believe that diet had much to do with these relapses.

As to Dr. Comfort's comments, I have a feeling that nontropical sprue is a group of diseases having poor intestinal absorption and steatorrhea as a common denominator rather than a single disease. Folic acid will not benefit patients who appear to have sprue but in reality have some other disease, for instance lipophagic granulomatosis. The two patients I mentioned were from Cincinnati and would be classified as nontropical sprue; they both fared better on folic acid than they had in five years on liver extract.

DR. ROBERT W. HEINLE, Cleveland, Ohio.—We have forty patients with pernicious anemia who have been under treatment with folic acid for from seven to nine months. They had received liver extract for many months or years before folic acid was given. In the short period they have been on folic acid, none of them has shown neurologic relapse. I do not want you to think that I am overenthusiastic about this drug. I do not think it has been proved to be as good as liver extract, but I do agree with Dr. Palmer that we have not tested it out thoroughly, particularly as to the route of administration and the dosage.

Dr. Palmer criticized the case of the one patient to whom we gave 12 mg. daily. His is a valid criticism, but that patient had been on an experimental regimen for fifty-two days without benefit. Other patients on that dose had received more benefit. Whether this one patient would have received more benefit if the folic acid had been given in larger doses I do not know.

The method of assaying conjugated folic acid in the urine is the standard method utilizing *Lactobacillus casei*. We have attempted to make these same studies on feces. This is difficult because of the high bacterial content. We are working on that problem at present and our preliminary study would indicate that very little folic acid is present in the stool.

With reference to Dr. Comfort's remarks about nontropical sprue, I have had a limited experience. Tremendous doses of liver seem to be necessary to obtain satisfactory results in many cases. Intravenous administration of crude liver extract has been recommended. The feeling has been that intravenous doses of crude liver extract in large amounts may be better than the administration of purified liver extract.

There is one thing I would like to say about the clinical use of folic acid. The dose schedule recommended by the manufacturer is too low. They recommend daily doses of 5 to 20 mg. or intramuscular doses of 15 mg. daily. It is possible that some patients can be brought into remission on that dose, but it is more likely that a great many will need larger doses than this, and I do not think we should pay too much attention to the recommended schedule. It should be noted that the manufacturers of folic acid suggest that better results may be obtained by the simultaneous administration of folic acid and liver extract than with folic acid alone.

RUTIN IN PURPURA

F. W. MADISON, M.D., AND H. W. POHLE, M.D. (By Invitation),
MILWAUKEE, WIS.

It is probable that one of the etiologic mechanisms capable of producing the vascular fragility characteristic of purpura is of deficiency type. For many

years avitaminosis C was considered to be of major importance, but recent studies have suggested that it is much less frequently a factor than was previously supposed. In 1936 Szent-Györgi observed that citrin derived from paprika or lemon was capable of reversing experimentally produced vascular fragility. He designated it as vitamin P and suggested that deficiency of that substance was responsible for purpuric changes in some instances. Two crystalline flavone glucosides derived from citrin, hesperidin, and eriodictol have failed to produce the same effect noted in the use of citrin. Recently a flavonol glucoside, rutin, closely related to hesperidin, has been used in a similar manner and has seemed to be more effective than either of the flavone glucosides. It has been used in 173 reported cases of purpura with reversal of fragility in 152 cases (88 per cent).

Our clinical experience with rutin has been limited by the supply available, but the results thus far have been of such nature as to suggest that it does exert a favorable influence on vascular fragility in some types of purpura. Its effect has been studied in fourteen cases of clinical purpura, six of which were of probable allergic origin, two toxic, one endocrine, one associated with hypertension and retinal hemorrhages, and four associated with advanced malignant disease. The most striking results were obtained in the last group where cessation of the drug resulted in relapse and resumption in remission. Less convincing results were seen in the allergic group and questionable results in the remaining groups.

THE EFFECT OF TOTAL BODY X-IRRADIATION ON A PRE-EXISTING INDUCED ANEMIA

LEON O. JACOBSON, M.D., EDNA K. MARKS (BY INVITATION), AND
ERIC L. SIMMONS, PH.D. (BY INVITATION), CHICAGO, ILL.

One of the problems facing those of us charged with the responsibility of the protection of personnel from radiation hazards on the plutonium project was whether individuals with a pre-existing anemia would be more adversely affected by externally originating total body irradiation than individuals with normal values. In an attempt to study this problem, a regenerative anemia was produced in rabbits by the subcutaneous administration of phenylhydrazine hydrochloride. The hematologic effects of 800 r. total body x-irradiation on such anemic animals were compared to effects on animals given only phenylhydrazine and allowed to recover spontaneously and to a group of animals given 800 r. alone. A group of normal untreated animals was studied simultaneously.

The characteristic initial rise and subsequent reduction in heterophils and immediate precipitous fall in the lymphocyte values followed the administration of 800 r. in the group in which a regenerative anemia had been produced with phenylhydrazine as well as in normal control animals. The time of recovery of those elements to normal limits in the two groups was likewise comparable. An "abortive rise" in the leucocyte values of both of these groups was noted between the fifth and eleventh days after the irradiation.

The group of animals which received x-irradiation alone developed an anemia with its maximum at fourteen days and with recovery by twenty-three days. The animals in which a regenerative anemia was produced by phenyl-

hydrazine and which were irradiated at or near the point of maximum anemia developed no further anemia, values returning to normal limits by twenty-three days. The erythrocyte and hemoglobin values of the group in which an anemia was produced by phenylhydrazine and which were allowed to recover spontaneously, however, returned to normal within fourteen days.

The reticulocyte values of animals which received phenylhydrazine had reached approximately 21 per cent when the x-irradiation was given and were reduced to a minimum value of 1.0 per cent within two days after the irradiation. Recovery to normal limits occurred by nine days in this group. The reticulocyte values of normal control animals which were given 800 r. fell maximally within two days, reached a minimum of less than 0.1 per cent, and recovered slowly but completely by twenty-three days.

The failure of 800 r. total body x-irradiation to produce further anemia in animals with a previously induced regenerative anemia or to materially interfere with recovery is dependent in part on the number of surviving erythroblasts in the erythropoietic tissue.

Histologic studies made on animals prepared in a comparable manner and sacrificed at varying appropriate intervals indicate that erythropoietic tissue was completely destroyed by seventy-two hours in the normal rabbits which received 800 r. and recovery proceeded slowly. On the other hand, although massive destruction of erythropoietic tissue occurred after exposure to 800 r. in animals in whom a regenerative anemia had been produced with phenylhydrazine, this destruction was delayed beyond seventy-two hours. This appears to indicate that a latency to x-ray effect was produced in erythropoietic tissue which had previously been stimulated.

ON THE RELATION OF CALCIUM TO THE ACTIVATION OF PROTHROMBIN AND ITS SIGNIFICANCE IN DICUMAROL POISONING

ARMAND J. QUICK, M.D., MILWAUKEE, WIS.

The role of calcium in the coagulation mechanism has not been satisfactorily defined, and the generally accepted concept that prothrombin is activated by thromboplastin in the presence of ionic calcium has failed to advance knowledge concerning the chemical action of calcium in its participation in coagulation. The recent finding (Steinberg) that a phenol-formaldehyde resin known commercially as Amberlite can quantitatively remove calcium from blood, without producing any other demonstrable change, offers a new means for studying quantitatively the calcium requirement for coagulation and specifically for the activation of prothrombin.

It was found that a fixed amount of calcium is required for the optimum activation of prothrombin, that is, for the shortest prothrombin time. For human plasma it is approximately 0.0012 M. and for dog blood 0.0004 M. Higher concentrations have no further effect except that a depressive action begins when the calcium ion concentration exceeds 0.02 M. Below the optimum or critical concentration of calcium, the prothrombin time becomes progressively delayed. Since this critical level is below the concentration of the

free or ionized calcium, it appears that ionized calcium is not involved in coagulation. One can conjecture that plasma contains a calcium cofactor which with thromboplastin and calcium becomes the activator of prothrombin. Evidence was obtained that this cofactor is not directly dependent upon either component A or B of prothrombin.

When Dicumarol was fed to dogs, the minimum or critical concentration of calcium required for optimum activation of prothrombin increased as the prothrombin (or more accurately component B) decreased. When the prothrombin time became twenty seconds, the normal concentration of the calcium of the blood was no longer sufficient for optimum prothrombin activity. This suggests that the delayed coagulation in dicumarol poisoning may not be solely the resultant of prothrombin depletion but may be influenced by an inadequate concentration of calcium. On the basis of these results, the unreliability of the bedside method for the determination of prothrombin becomes obvious, since in this test thromboplastin without additional calcium is added directly to blood.

DISCUSSION

DR. CHARLES F. CODE, *Rochester, Minn.*—I should like to ask if Dr. Quick has tested the effect of changes in the concentration of prothrombin upon the optimum calcium concentration in an artificial setup using purified constituents in which the prothrombin concentration might be varied at will. I wonder if a shift in the amount of prothrombin alone would alter the optimum calcium concentration.

DR. KENNETH M. BRINKHOUS, *Iowa City, Iowa.*—Since amberlite is very effective in removing electrolytes, I wonder if you have data on the concentration of other plasma electrolytes in the amberlite-treated plasma. This factor might have had an effect on some of these results, as electrolyte concentration is known to influence considerably the rates of several of the clotting reactions.

DR. QUICK.—In regard to Dr. Code's question about an artificial setup, we have had no experience. This work is still preliminary and we need to do much more on it. Probably we can set up certain experiments to get further information.

In answer to Dr. Brinkhous' remarks, we use amberlite treated with saline and so far as we know the action is primarily an exchange one, an atom of sodium for one of calcium. It gives off one atom of sodium and takes up one of calcium. There may be other changes, and probably the action is not as simple as that, but in our work we found no evidence of action other than the one of exchange.

MORPHOLOGY OF BONE MARROW

IMPRINT AND HISTOLOGIC PREPARATION OF ASPIRATED STERNAL MARROW UNITS
E. M. SCHLEICHER (BY INVITATION), AND E. A. SHARP, M.D., DETROIT, MICH.

It has been established that direct and indirect (heparinized and centrifuged) bone marrow spreads and differential counts made within a measured area offer a means of distinguishing morphologic differences as well as quantitative relationships.

At the same time these methods fail in two important features, namely, (1) the preservation of cellular cyncytia which permit a study of marrow cell development and (2) maintaining intact the histologic pattern of sternal marrow units. These latter configurations are essential in the diagnosis of early infectious or malignant processes of this hemopoietic organ.

It is the purpose of this paper to present representative examples of "imprint" and intact "histologic" preparations of sternal marrow in black and white and kodachrome, showing the methods of preparation and the normal compared with the pathologic morphology. It will be demonstrated that maturation arrest in pernicious anemia does not occur at the megaloblastic (pronormoblastic) stage but rather that the reticulum is pathologically activated. Metastatic carcinoma, tuberculosis, and various patterns in blood disorders will be presented.

THE EFFECT OF RADIATION THERAPY ON THE NOCTURNAL GASTRIC SECRETION IN PATIENTS WITH DUODENAL ULCER

ERWIN LEVIN, M.D. (BY INVITATION), WALTER LINCOLN PALMER, M.D.,
AND JOSEPH B. KIRSNER, M.D., CHICAGO, ILL.

The fasting nocturnal gastric secretion was studied in twenty-eight patients with active uncomplicated duodenal ulcer. The twelve-hour volume ranged from 550 to 1,750 c.c. with an average of 1,110 cubic centimeters. The free acidity varied from 18 to 122 clinical units, the average being 62. The night secretion was studied in nine of these patients during the period they received x-ray therapy directed at the fundus and body of the stomach. A reduction in volume ranging from 6.3 to 51.6 per cent was obtained in seven patients during the first week of therapy. In two patients an increase in volume was noted. A reduction in free acidity was observed in seven patients. Nocturnal gastric secretion was studied in fifteen patients of the group at varying intervals after therapy. A decrease in volume occurred in fourteen patients, the average reduction being 52.1 per cent. In one patient the volume was increased but the free acidity disappeared. There was a marked reduction in the free acidity of the nocturnal secretion in all patients, the reduction amounting in thirteen of the fifteen to anacidity. A comparable reduction was observed in the gastric secretory response to histamine. These studies indicate that radiation therapy decreases the gastric secretion as measured in the fasting state and by the response to histamine. The duration of the effect is variable.

DISCUSSION

DR. LEON SCHIFF, Cincinnati, Ohio.—I would like to ask how your results in the reduction of volume and acidity of gastric contents compare with those seen following bilateral vagotomy.

DR. MOSES BARRON, Minneapolis, Minn.—I would like to ask if any other method than x-ray was used.

DR. GEORGE WAKERLIN, Chicago, Ill.—Were pepsin studies made on these patients and, if so, what were the results?

DR. LEVIN.—In answer to Dr. Schiff's question regarding the reduction of gastric secretion following x-ray therapy compared to the reduction following vagotomy, of course the effect of x-ray therapy is not permanent. Some patients, I have been told, have had a reduced gastric content for two or three years. It is still too soon to predict what the results of vagotomy will be. I had the opportunity to study one patient who had had vagotomy three years previously. His volume, free acid, and night secretion are still reduced, and there is no free acid in the night secretion.

As to the medical management, all of these patients were on Sippy management. While the studies were being carried on, no patient received any drug that would depress gastric secretion.

Pepsin studies are now being carried out in an effort to determine if that is reduced by x-ray therapy. I am told that there is some reduction in peptic activity.

THE MEASUREMENT OF HUMAN GASTRIC FUNCTION

ARTHUR M. SCHOEN, M.D. (BY INVITATION), AND P. K. KNOEFEL, M.D.,
LOUISVILLE, KY.

Past studies of human gastric function have been concerned largely with the aspiration of gastric contents and the measurement of volume and composition. The actual rate and nature of the secretion cannot be determined from these two observations alone, since gastric emptying occurs. Because of this, others have injected foreign substances into the stomach, such as readily determinable dyes, and have determined more accurately the composition of gastric juice but not the rate of secretion. It is possible to determine the secretory rate and emptying rate if a volume of isotonic NaCl solution (V_0) containing phenol red (W_0) is injected into the empty stomach and the residual contents of the stomach (V_t) containing phenol red (W_t) are aspirated at time (t). Then the volume secreted (S) in time (t) is

$$S = (V_0 - V_t) \left\{ \left[\text{Log} \left(\frac{W_t}{W_0} \right) \div \text{Log} \left(\frac{V_t}{V_0} \right) \right] - 1 \right\}$$

and the volume emptied (E) is

$$E = S - V_t + V_0.$$

The necessary assumptions are: (1) No gastric absorption of water or phenol red occurs, (2) no saliva or duodenal contents enter the stomach, (3) there is uniform distribution of phenol red throughout gastric contents during time (t), (4) secretion and emptying occur at constant rates throughout time (t), and (5) gastric contents are completely aspirated at time (t). A satisfactory technique for obtaining gastric juice was developed. This includes preparation of patient for basal conditions, selection and preparation of gastric tube, insertion of tube and determination of location by fluoroscopy, and procedure for complete aspiration. Evidence for the correctness of these assumptions and the validity of the method has been obtained.

From the previously mentioned data and the measured pH and peptic activity of gastric contents, the pH and peptic activity of gastric juice as secreted can be calculated. The resting rate of gastric secretion seen in forty observations in twelve normal persons was 2.09 c.c. per minute, standard deviation 0.96. In one person the daily average basal secretory rate on five days varied from 2.07 to 4.33 c.c. per minute. The average deviation in consecutive observations in the same person was 12.4 per cent. The average hydrogen ion concentration of the secretion was pH 1.51 in twenty-six observations. Studies have been made in patients with peptic ulcer during remissions and exacerbations and in a variety of conditions as aplastic anemia, cholecystitis, pancreatitis, and neurosis. The

responses of normal persons and patients with ulcers to sham feeding, antacids, alcohol, caffeine, histamine, atropine, and insulin have been studied before and after vagotomy.

DISCUSSION

DR. WALTER L. PALMER, Chicago, Ill.—Dr. Schoen and Dr. Knoefel have certainly made gastric analysis scientific. The fallacies of the older methods have been recognized and apparently corrected in this excellent contribution. I wonder if the essayist can answer the question of whether there is a higher level of gastric secretion in a patient with duodenal ulcers than in a normal individual.

DR. SCHOEN.—We have made 161 of these tests. We hesitate to do the work on people who have active duodenal ulcers. We have done some on such patients and those tests have shown definitely that with healing of the ulcer there is a decrease in the rate of gastric secretion.

THE EFFECT OF ENTEROGASTRONE ON FASTING GASTRIC SECRETION AND MOTILITY IN PATIENTS WITH DUODENAL ULCERS

H. MARVIN POLLARD, M.D., MALCOLM BLOCK, M.D. (BY INVITATION), AND
W. H. BACHRACH, M.D. (BY INVITATION), ANN ARBOR, MICH.

Enterogastrone has been reported to be effective in the prevention of jejunal ulcers in Mann-Williamson dogs and the prevention of recurrence of peptic ulcer in human beings. The possible mechanisms of its effect are (1) an inhibition of secretion of hydrochloric acid, (2) an inhibition of motility, and (3) an increased resistance of the gastric and duodenal mucosa to ulceration. It has been reported that Mann-Williamson dogs treated for several months with enterogastrone do not exhibit the excessive gastric secretory response to alcohol characteristic of most untreated Mann-Williamson dogs; furthermore, enterogastrone has been shown to inhibit the histamine-stimulated gastric secretion in normal human beings. Studies of the effect of enterogastrone on human motility have not been reported.

Our preliminary findings on three patients with intractable duodenal ulcers treated for at least three months with enterogastrone orally show no consistent reduction in the fasting output of hydrochloride by the stomach.

Simultaneous motility and secretion studies after a parenteral dose of 200 mg. of enterogastrone show only a transitory inhibition of motility and secretion. The effect of large doses has not yet been worked out.

The clinical course of the three treated patients has not been followed for a sufficient period of time to evaluate the therapeutic effects of the preparation.

The studies are being continued.

DISCUSSION

DR. JOSEPH B. KIRSNER, Chicago, Ill.—We have been interested in this problem of the effect of enterogastrone on gastric secretion in man. We have not had the oral preparation available. After studying a relatively large number of patients, using larger quantities of the parenteral preparation, we can confirm some of the observations of Dr. Bachrach; that is, the effect of enterogastrone in large doses is rather variable and unpredictable. In certain cases there is a pronounced decrease in the volume and level of gastric acidity even to the

absence of hydrochloric acid in the gastric content. One of the interesting things is that this effect may not become apparent for twenty-four to thirty-six hours after the onset of treatment. In our studies the tube has been kept in place for several days.

Another point I would like to make is that this effect of enterogastrone on gastric secretion is not a fixed one. In one patient with duodenal ulcers, during the course of the experiment an achlorhydria resulted, but during a disturbing psychiatric interview with the patient there was a marked rise in volume of secretion and in the level of hydrochloric acid. Later, after the interview had ended and enterogastrone was continued, there was again a drop in the volume of gastric secretion. This observation illustrates what I am sure is now well known, namely, the effect of the emotions on gastric function.

Dr. Bachrach mentioned an important point with regard to the local pain following the injection of this product. We have found this to be true, and on one occasion, after giving a large dose, the patient continued to be distressed ten days after the injection.

DR. BACHRACH.—We had achlorhydria in two patients, but they both had gastric ulcers. They got well without the benefit of enterogastrone.

EFFECTS OF ALLOXAN UPON THE HUMAN PANCREAS

JEROME W. CONN, M.D., D. L. HINERMAN, M.D. (BY INVITATION), AND
R. W. BUXTON, M.D. (BY INVITATION), ANN ARBOR, MICH.

It has now been established that a single dose of alloxan, varying from 50 to 400 mg. per kilogram, produces destructive changes in the pancreatic islets of the dog, monkey, pigeon, duck, guinea pig, cat, and rat. When administered in smaller daily doses a much larger total amount is required to produce evidence of islet cell damage. An occasional animal is found to be refractory.

The only reported observations of the effects of alloxan upon human islet tissue are by Brunschwig and associates (two cases). No histologic changes in the islet tissue were found (1) seven hours after a single injection of 600 mg. per kilogram and (2) one month after a total of 3,150 mg. per kilogram given irregularly over a fifty-day period. The impression has been gained, therefore, that human islet tissue is exceedingly resistant to the damaging effects of alloxan.

Our study was done on a patient harboring a secreting pancreatic insuloma. On each of nine consecutive days she was given alloxan intravenously in the following doses in milligrams per kilogram: 50, 50, 100, 100, 100, 100, 100, 100, 100. Fifteen days after the last injection an islet cell tumor was removed surgically and a section of pancreas was obtained for study.

Microscopic examination of the tissue, stained differentially by several methods, shows no recognizable effect of alloxan upon the islet cells of the neoplasm. However, clear evidence of marked destruction of the islets of the pancreas proper and of early repair are observed. The pathologic changes seen in these islets are typical of those which occur in alloxan-treated animals and resemble most closely those described by Baily and associates as occurring in rabbits given small daily injections for from seven to thirteen days.

The metabolic studies complement the pathologic findings. In the 15-day interval after alloxan and before operation, the insuloma continued to secrete insulin as indicated by the continuation of an extremely low daily level of the fasting blood sugar. In this same period, however, and despite the low fasting blood sugar, a marked decrease in carbohydrate tolerance was apparent. Upon removal of the tumor frank diabetes developed requiring large amounts of

insulin despite low carbohydrate intake. Insulin was discontinued on the forty-fifth postoperative day. To date (sixty-five days postoperative) carbohydrate tolerance has improved but mild diabetes persists.

Conclusions.—

1. In this study the sensitivity of human islet tissue to the destructive effects of alloxan approximates that observed in other species.
2. Neoplastic islet tissue is much more resistant to alloxan than is normal islet tissue.
3. In future attempts to use alloxan therapeutically these facts should be considered.

DISCUSSION

DR. GEORGE GOMORI, Chicago, Ill.—I had a patient dying of carcinoma of the breast with metastases. She was given 500 mg. of alloxan per kilogram of body weight and died thirteen hours later. Autopsy showed no trace of change in the islands of Langerhans. I wonder whether changes shown here cannot be due to massive intravenous infusions of glucose. I have seen a number of specimens from patients who had to be treated with massive doses of glucose. In three or four of these cases the changes were very much like the ones shown here, although the patients did not receive alloxan. Similar degenerative changes are occasionally seen also in animals treated with large doses of insulin. The changes presented here also may be due to massive amounts of insulin released by the tumor.

DR. CONN.—This patient did not receive intravenous glucose therapy in the preoperative period. In attempting to settle the problem of whether hyperinsulinism, per se, may produce similar islet cell changes, we are carrying out long-term experiments in dogs. Preliminary evidence indicates that normal dogs given sufficient protamine insulin daily to keep the fasting blood sugar in the same range as this patient's had been show no islet cell changes similar to those seen in the patient following the course of alloxan.

BOOK REVIEWS

Medical Jurisprudence and Toxicology. Eighth edition. By John Glaister, J.P., D.Sc., M.D., F.R.S. (Ed.), Of the Inner Temple, Barrister-at-Law, etc., Regius Professor of Forensic Medicine, University of Glasgow; formerly Professor of Forensic Medicine, University of Egypt, Cairo; and Medico-Legal Consultant to the Egyptian Government. Williams & Wilkins Company, Baltimore, 1945. Price \$8.00. Cloth with 222 illustrations and 691 pages.

This well-illustrated book is intended to cover the main aspects of Forensic Medicine. It is divided into two parts. The first part deals with medical jurisprudence and describes the methods used to determine the cause of death produced by asphyxia, drowning, burning, electricity, hanging, exposure to cold, or by homicidal injuries. Furthermore, injuries produced by firearms, the identification of blood and seminal stains, and the medico-legal aspects of sex crimes are reviewed. The second part of the book is concerned with toxicology. The etiology, the clinical signs, and the treatment, as well as the post-mortem appearances, and the chemical diagnosis of poisonings are described.

The usefulness of the book in this country is limited by the fact that it considers exclusively the British laws. The clinical aspects of toxicology are adequately presented, but many chemical tests described lack specificity or sensitivity and appear to be of relatively little utility in the detection of poisons in biological materials.

ERNEST BUEDELING, M.D.

RAPID IDENTIFICATION OF SHIGELLA IN A PUBLIC HEALTH LABORATORY

W. W. FERGUSON, PH.D., MARY BRANSTON, A.B., GRACE L. MCCALLUM, B.S.,
AND MARGARET J. CARLSON, B.S.
LANSING, MICH.

BOYD'S concept of the antigenic structure of Flexner dysentery bacteria has been given practical application in this country by Wheeler.¹ He² recognized that the essential differences between Flexner types of *Shigella* are the specific antigens, while the group components are of secondary importance, except perhaps in the differentiation of Flexner W into subtypes. Wheeler¹ has described methods for serologic identification of other pathogenic *Shigella*, as well as the Flexner and Boyd types,* by means of a slide agglutination test employing formalinized antigens and properly absorbed sera. He has specified, however, that "classification of the organisms as determined by the agglutination test should be confirmed by fermentation reactions."

Weil and associates³ are in apparent agreement with Boyd and Wheeler that specific or "primary" antigens distinguish the Flexner as well as the Boyd types from each other. However, some of the dual antigens recognized by Weil and co-workers would be regarded, necessarily, as group antigens by Wheeler. In effect, the former authors have combined the concept of Boyd with that of Andrewes and Inman.⁴

Weil and associates³ have advocated the use of absorbed sera for rapid identification of *Shigella*. More recently, Weil and co-workers⁷ have established the existence of minor antigens which interrelate *Shigella ambigua*, *Shigella alkalescens*, and *Shigella dispar* with certain of the Boyd types. They caution that species (and type) identification must rest on both immunologic and cultural properties.

Nelson and associates,⁸ who examined 450 "presumptively positive" enteric cultures in India, feel that the use of absorbed sera in the spot agglutination test for identification of *Shigella* is far superior to the use of unabsorbed sera in the conventional tube agglutination method. Eighty per cent of the cultures examined by these investigators were identified as *Shigella*, presumably by serologic means alone.

Extensive use of *Shigella* typing sera was made in Army laboratories in various parts of the world during World War II. Outside of one brief publication,⁹ no information on the sera and their uses has appeared in the literature.

From the Bureau of Laboratories, Michigan Department of Health.

Received for publication, Jan. 4, 1947.

*Throughout this paper the Flexner types will be designated as Flexner V, W, X, Y, and Z and the Boyd types as 103, P119, SS, 170, P285, D1, D19, P274, and P143. At present the different systems for designating Flexner and Boyd types, as proposed by Boyd,¹ Wheeler,² and Weil and associates,³ are in disagreement. The effect on the literature of the various systems may be judged from the following example. Francis⁴ has announced the discovery of two new antigenic types of *Shigella* with the provisional designations of *Shigella flexneri* type VII and *Sh. flexneri* type VIII. According to Weil types VII and VIII are the same as the Flexners X and Y of Andrewes and Inman⁴ which Weil and associates regard as types possessing specific antigens.

The Army sera were made for use in a slide agglutination technique for provisional identification of dysentery organisms, to be followed by determination of motility and confirmatory biochemical studies.

Our experience¹⁰ in this laboratory in the preparation and use of Flexner and Boyd typing sera led us to believe that Wheeler's views on the serology of the Flexner group were better applicable to diagnostic problems than those of Weil and associates.³ It appeared to us that Wheeler's absorption scheme could be extended and that antisera could be produced which would be free of practically all minor agglutinins. A Flexner antiserum, for example, could be absorbed not only with other cross-reacting heterologous Flexner types for removal of group agglutinins but with any heterologous *Shigella* which gave a reaction in the serum. Such an antiserum should be free of agglutinins for all dysentery organisms except the homologous type. Absorbed antiserum for other species, such as *Shigella dysenteriae*, could be produced by the same method. It was recognized that paracolon and other organisms of the Enterobacteriaceae might possess minor antigens in common with *Shigella*. Only trial of absorbed sera could determine if cross-reactions would occur with bacteria of other genera.

During a period of preliminary trial the typing of dysentery bacteria was attempted with absorbed sera only after biochemical studies had been made. When no disagreements between cultural and serologic tests were noted during the period of trial, it was decided to classify *Shigella* on the basis of serologic reactions alone.

This paper reports the examination of 315 enteric cultures by slide agglutination technique with absorbed *Shigella* sera. By means of this rapid method of examination a report was made on the identity of *Shigella* present in a fecal specimen approximately forty-eight hours after the specimen was received in the laboratory. Eventual fermentation and tube agglutination studies were made on every organism included in the study.

METHODS

Sera.—The following absorbed sera were provided the Central Diagnostic Laboratory: *Sh. dysenteriae*, *Sh. ambigua*, *Sh. alcalescens* (Type I), *Shigella sonnei*, polyflexner (prepared with V, W, X, Y, Z, 103, P119, and 88 strains), monovalent Flexner V, monovalent Flexner W, monovalent Flexner Z, monovalent Boyd 103, monovalent Boyd P119, and monovalent Boyd 88. Additional absorbed sera were prepared for the mannitol-negative types Sachs Q454, Q771, Q902, Q1030, and Q1167, together with absorbed sera for Boyd types 170, P288, D1, D19, P274, and P143. A polyvalent serum was also prepared to cover Boyd types 170 through P143. The Sachs and Boyd type sera, other than Boyd 103, P119 and 88, were not used routinely.

Source of Cultures.—The same stock strains used for production of sera in an earlier study¹⁰ were employed, plus additional cultures.*

*Contributed by Dr. Kenneth M. Wheeler, Connecticut State Department of Health, Hartford; Captain G. V. Seastone, Medical Corps, Army Medical Center, Washington, D. C.; Dr. C. A. Peluffo and Dr. Estenio Hormaeche, Institute of Hygiene, Montevideo, Uruguay; and Dr. Joseph Felsen, The Bronx Hospital, New York City.

Production of Antisera.—White rabbits weighing approximately 6 pounds were used for production of antisera. The usual immunization procedure was as follows: A series of three intracutaneous inoculations were made on alternate days with formalinized saline suspensions of cultures grown on blood agar medium. These were followed by six to seven intravenous inoculations of living organisms also grown on blood agar. Intravenous inoculations were made on alternate days.

Suspensions were standardized to the turbidity of a No. 2 McFarland standard, and care was taken not to suspend agar along with organisms. The total amount of inoculum was usually 9.0 cubic centimeters.

Immune sera after processing were preserved with chloroform.

Preparation of Absorbed Sera.—Table I on the preparation of a Flexner V antiserum will serve as an example of the steps taken in preparing an absorbed serum. Unabsorbed serum, diluted 1:10, was tested by slide agglutination technique against eighteen-hour, living, smooth strains of *Shigella* grown on blood agar. None of the cultures was heated before use to destroy heat-labile "blocking" antigen, since the cultures listed, including *Sh. alkalescens* R strain, have shown no evidence of possessing such a substance.

The technique of the test was the same as that employed in identification of unknown dysentery cultures by the finished serum. The wells of agglutination slides* were filled two-thirds full of serum and test organisms were rubbed into the edges of serum drops by means of a loop or straight inoculating wire. An even, milky suspension of organisms resulted which was, admittedly, somewhat uneven in turbidity from well to well. The slide was rocked by hand and observed for fifteen minutes. The system of recording reactions was by plus signs: 4 plus denoted complete agglutination, 2 plus partial agglutination, doubtful a barely detectable clumping. Since speed of reaction was some indication of the potency of a serum, the words "instant," "moderate," and "slow" were used to denote reactions taking place, respectively, as soon as suspension was accomplished, within one minute, or after approximately five minutes.

Following the determination of reactions in unabsorbed serum, strains were selected for removal of cross-reacting agglutinins. With Flexner antisera the X and Y strains were always used for initial absorptions. Organisms for absorption were grown on veal infusion agar in Blake bottles; they were then washed off the agar with saline and spun down in an anglehead centrifuge. The supernatant fluid was poured off and unabsorbed serum, diluted 1:10, was added to the packed bacteria. Resuspension of the bacteria was accomplished by stirring. Incubation was carried out at 50° C. for one hour. An excess of the absorbing dose of bacteria was used for each step in freeing a serum of cross-agglutinins.

After incubation of serum and antigen, bacterial cells were removed by centrifugation, and the serum was tested against each strain which had reacted in the initial titration. In the case of Flexner V antiserum. Lot 3, absorption was completed by a second absorbing dose consisting of Flexner Z and *Sh. alkalescens* organisms. Slide agglutination tests were carried out with Flexner V antiserum and the antigens which had reacted following absorption with X

Titer of Flexner V antiserum, absorbed, with homologous strains, 1-2560.

Determination made by tube dilution method, incubation 50° C. for eighteen hours.

*Absorbing strains: Flexners X694, X1533, X1806, X1807, Y R, Y F1219, and Y412.

†Absorbing strains: Flexner Z and *Sh. alkalescens*.

and Y strains. At this stage the serum appeared free of minor agglutinins, while the reaction with Flexner V organisms was instant and complete. The serum dilution was doubled and tests were again made with Flexner V antigens. When agglutination took place within one minute and was complete, a dilution of 1:20 was selected as the "working dilution."

Only rarely has it been necessary to accept an antiserum diluted 1:10; on the other hand, no serum was diluted more than 1:20 because of possible deterioration. As a preservative, merthiolate in powder form was added to antiserum to make a final concentration of 1:1,000. It was then filtered through a Seitz pad and a final titration made by testing the serum against its homologous strains by tube agglutination technique.

In the example given in Table I, a total of thirty-five strains are listed as antigens. The number has varied from lot to lot of antisera, as new antigenic types have been added to our collection. At present we employ forty-six strains as titration antigens. Storage of these strains dried in vacuo from the frozen state has aided greatly in prevention of dissociation.

The inclusion of *Salmonella typhi* among the stock strains was done originally as an experiment. It was thought a worth-while precaution to remove minor agglutinins for *S. typhi* from Shigella sera since identification of dysentery cultures was to be made from triple sugar slants and since occasional strains of the typhoid organism are found which are dysentery-like in their reactions, failing to produce H_2S in twenty-four hours. When it was found that strong cross-reactions for *S. typhi* develop in some of the Flexner sera, *S. typhi* 703 was included in all titrations. Whether or not the cross-reactions with *S. typhi* are due to antibodies similar to the alpha agglutinins reported by Stamp and Stone¹¹ has not been determined.

Performance of the Diagnostic Slide Agglutination Test.—The technique of the diagnostic slide agglutination test has varied somewhat with the bacteriologist. In general the method has been as follows: Organisms producing dysentery-like reactions on triple sugar slants were selected for typing. Each culture was tested in trypanflavine solution (1:500 concentration of acriflavine hydrochloride in 0.85 per cent NaCl solution) and in physiologic saline solution for indications of autoagglutinability. It was discovered early in our experience with trypanflavine solution that *Sh. alkalescens* strains possessing heat-labile "blocking" substance were clumped rapidly in trypanflavine,* yet remained in even suspension in normal saline. Organisms clumping in trypanflavine and not in saline were either (1) placed in saline suspension and boiled for fifteen minutes, then tested with absorbed *Sh. alkalescens* antiserum; or (2) identified by conventional methods, that is, by observation of biochemical activities and reaction in specific serum by tube method. Only strains of *Sh. alkalescens* identified by slide agglutination are included in this report.

Cultures which did not clump in either trypanflavine or saline were tested in polyflexner, *Sh. sonnei*, and *Sh. alkalescens* absorbed sera. Organisms which were agglutinated in either of the last two sera were reported by species. A culture which agglutinated in polyflexner serum was tested in the three monovalent Flexner (V, W, and Z) and three Boyd sera (103, P119, and 88). An organism which reacted in the polyvalent serum and a monovalent serum was reported by species and type, that is, *Sh. paradysenteriae*, Boyd 103. With but few exceptions the reactions in monovalent sera were complete in one or two minutes or less. Flexner W strains were more variable in agglutinability than other types. Occasional strains were clumped rapidly; others, while smooth by test in saline, were slow to react.

Biochemical Tests.—All cultures discussed in this report were tested for fermentative reactions in semisolid agar medium containing glucose, lactose, sucrose, maltose, mannitol, and xylose, respectively. Organisms selected for

*Since some *Sh. dysenteriae*, *Sh. ambigua*, and Sachs strains have been reported as occurring with heat-labile antigens, it is possible that occasional strains will clump in trypanflavine. VI strains of *S. typhi* clump rapidly in trypanflavine.¹²⁻¹⁴

special study, such as strains of Boyd 88 and *Sh. alkalescens*, were inoculated in liquid carbohydrate media. In the case of Boyd 88 cultures, dulcitol was added to the list of carbohydrates. An occasional strain of particular interest, such as C-27, together with strains of *Sh. alkalescens*, were tested with a wide range of carbohydrates. Observation of indol production and hydrolysis of urea was done routinely, whereas reactions on Simmons' citrate were observed only on cultures selected for special study. Tests for motility were made on *Sh. alkalescens* cultures and on all strains whose biochemical pattern was at variance with the evidence of tube or slide agglutination.

Macroscopic Agglutination.—Tube agglutination tests were carried out at 50° C. in the water bath for eighteen hours on all organisms with dysentery-like reactions in triple and single sugar media. The following antisera were available: *Sh. dysenteriae*, *Sh. ambigua*, *Sh. alkalescens*, *Sh. sonnei*, and polyflexner.

RESULTS

A total of 315 cultures which gave dysentery-like reactions in triple sugar agar slants was examined by slide agglutination technique with absorbed sera. Of these, 307 were accepted as *Shigella* on the basis of their agglutination in the spot test. The serologic identification of the 307 cultures was as follows:

<i>Sh. sonnei</i>	159
<i>Sh. paradyenteriae</i> (Flexner and Boyd)	115
<i>Sh. alkalescens</i>	32
<i>Sh. ambigua</i>	1
Total	307

The paradyenteria types were identified by monovalent sera as:

Flexner V	1
Flexner W	26
Flexner Z	28
Boyd 103	8
Boyd P119	0
Boyd 88	52
Total	115

Five cultures which are included in the total of 315 were agglutinated in polyflexner antiserum on slide test. Four of these failed to react in monovalent sera and were, therefore, not reported as *Shigella*. Fermentation studies revealed that they were aerogenic and belonged to the paraecolon group. The fifth culture, 8255, reacted slowly in Flexner W antiserum and was reported as a Flexner W. Subsequent biochemical studies demonstrated that it, also, was a probable paraecolon. On first isolation this culture was anaerogenic in triple and single sugars, but it fermented glucose, maltose, and mannitol with production of acid and gas, upon transfer. The organism failed to ferment lactose, sucrose, dulcitol, and salicin in twelve days and did not utilize citrate or hydrolyze urea. It was indol positive, nonmotile, and reduced trimethylamine oxide to trimethylamine. Absorption studies with 8255 and Flexner W organisms and their antisera demonstrated that 8255 culture has a minor antigenic

relationship for Flexner W. Agglutinins for 8255 and Flexner W organisms were not present in the serum of the rabbit used for production of 8255 immune serum.

Also included in the total of 315 organisms are two paradysentery cultures which could not be identified by slide agglutination technique. One reacted in polyflexner antiserum but failed to agglutinate in the six monovalent sera. Although it was a typical paradysentery organism biochemically, and smooth in phase, it apparently possessed no type-specific antigen. This strain was classified as Flexner Y on the basis of its 3,4 group antigens. The second paradysentery culture was typical biochemically and unstable in saline suspension upon first isolation. After rapid transfer it was agglutinated in polyflexner antiserum by the tube method. No type determination was made.

Only one of the more exotic *Shigella* was identified in the study of 315 cultures. This organism did not react with the absorbed sera used routinely and was, therefore, put aside for biochemical tests. Of the carbohydrates, glucose, lactose, sucrose, maltose, mannitol, xylose, and dulcitol, it fermented glucose only in twenty-four hours. In ninety-six hours, maltose was fermented weakly. Its other characteristics were those of a *Shigella*. Of the absorbed sera prepared against mannitol-negative *Shigella*, it was agglutinated only in Sachs Q771 serum. An antiserum prepared against our strain 7005 agglutinated a stock strain of Q771 to approximately the titer of the homologous organism. Reciprocal absorption tests demonstrated that 7005 and the stock strain possessed similar antigens.

Since Sachs Q771 strains have been reported infrequently in this country,^{15, 16} the source was of interest. Isolation was made from the fecal specimen of a 7-year-old Mexican child hospitalized with dysentery.

The identification of culture 8255 as a Flexner W was a definite error in classification due, unquestionably, to the use of inadequately absorbed W serum. A second error, also brought about by reliance on serologic identification alone, must be viewed in a different light. Among the 159 organisms classified as *Sh. sonnei* was a culture which gave atypical reactions biochemically. This culture, C-27, was found to be motile and anaerogenic, fermenting glucose, lactose, and maltose of the commonly used carbohydrates. By absorption studies it was found to possess the major antigen of *Sh. sonnei*, phase I, as defined by Wheeler and Mickle.¹⁷ A description of C-27 will be made in detail in a separate publication since this organism poses an interesting problem in classification.

Biochemical Tests.—

Flexner Types: All of the sixty-five Flexner organisms typed with absorbed sera were typical in their fermentation reactions, fermenting glucose and mannitol, or glucose, maltose, and mannitol. None fermented xylose. The majority produced indol.

Boyd 103: Boyd 103 types were irregular in their reactions. Six strains from the same source fermented glucose only of the carbohydrates used routinely. Mannitol was not fermented after prolonged incubation; indol was formed by

all six strains. Antisera were produced against two of the cultures and absorption studies were carried out with stock antisera and stock cultures of Boyd 103. The mannitol-negative strains were able to exhaust the agglutinins of a Boyd 103 stock antiserum for both stock cultures and mannitol-negative strains. The same results were obtained when sera for the mannitol-negative Boyd 103 types were absorbed with stock cultures.

Two of the eight Boyd 103 types identified were typical in their reactions, fermenting glucose and mannitol in twenty-four hours. One strain produced indol and the other did not.

Boyd 88: All but three of the fifty-two Boyd 88 types classified serologically were from a single outbreak, and, as might be expected, the forty-nine strains from the outbreak were fairly similar in biochemical characteristics. All fermented glucose and mannitol promptly; the majority fermented maltose in six or seven days, whereas dulcitol was attacked slowly by most strains and a few did not ferment the carbohydrate in fourteen days.

None of the fifty-two strains produced indol. One strain, not from the outbreak, fermented glucose and mannitol only. The irregularity of fermentative reactions by organisms of the Boyd 88-Newcastle-Manchester series has been noted by numerous investigators^{5, 18, 10} and has been attributed as regards gas production to the brand of peptone used as a base for fermentation media.²⁰ Two non-motile, gas-forming cultures were examined by us which were identified serologically as type Boyd 88. Both appeared anaerogenic on triple sugar medium in twenty-four hours but produced a small amount of gas in forty-eight hours. Both fermented glucose and mannitol promptly, eventually producing a considerable bubble of gas in the Durham vials. Neither culture fermented dulcitol in eight days. Absorption studies demonstrated that both organisms possessed the major antigen of type Boyd 88.

Shigella sonnei: With the exception of culture C-27, the organisms identified as *Sh. sonnei* were typical in their reactions during a short period of incubation. All fermented glucose, maltose, and mannitol in twenty-four hours; none fermented xylose or produced indol. Prolonged incubation of the Sonne cultures was not made to obtain reactions in lactose and sucrose.

Shigella alkalescens: Stuart and associates²¹ have pointed out that the antigenic and biochemical limits to the species *Sh. alkalescens* are difficult to fix. They report a study of 141 cultures corresponding to the classical description of *Sh. alkalescens* and forty-two cultures intergrading biochemically from *Sh. alkalescens* to *Escherichia coli* which possessed some or all of the antigenic fractions of *Sh. alkalescens*. It would appear that the identification of this species according to the strict definition is impossible by serologic means alone.

In order to discover what had been labeled as *Sh. alkalescens* by the slide agglutination test, strains isolated by us were examined in a wide range of carbohydrates and were grown on Simmons' citrate, urea medium, Voges-Proskauer broth, and semisolid motility agar. The majority of the cultures were typical in reaction, fermenting glucose, maltose, mannitol, and dulcitol, forming indol, and failing to grow on citrate or to produce acetyl-methyl-carbinol. They

were nonmotile. There were ten exceptions which were atypical in reaction with the difference that they grew on citrate in three to five days and were motile.

Shigella ambigua: The one *Sh. ambigua* culture identified serologically was typical in its biochemical reactions and was nonmotile.

Tube Agglutination: The 307 organisms classified as *Shigella* by slide agglutination technique were agglutinated to complete or moderate titer with appropriate antisera, with but few exceptions. An occasional strain was found to be partially dissociated by the time the tube method was employed and required transfer before a repeat test. Boyd 88 strains were not agglutinated strongly in the polyflexner serum employed for the tube agglutination titer, the average end point being 1:320. In contrast, Flexner strains were agglutinated in a dilution of 1:1280 to 1:5120 in the same serum. The average end point for *Sh. sonnei* strains in specific serum was a dilution of 1:5120. All of the *Sh. alkalescens* strains were agglutinated strongly in unabsorbed specific serum.

DISCUSSION

The rapid identification of *Shigella* by the use of absorbed sera has become an established procedure in some laboratories, since there are definite advantages in its employment in the slide technique over the tube method with unabsorbed sera. It is now a question with those who have adopted the slide agglutination technique of how far shall we go in accepting the results of serologic classification. Shall we report the identity of an organism as *Shigella* solely on the results of serologic identification with highly absorbed sera, or shall we combine serologic identification with biochemical confirmation studies to arrive at the identity of a dysentery-like organism?

The first course is attractive because of the rapidity with which a report may be made to a physician. Instead of a period of seventy-two to ninety-six hours between receipt of a specimen and a report on the *Shigella* present, there is the possibility of a report in forty-eight, or even twenty-four, hours if typing is made direct from an isolation plate. To offset the advantage of speed there is the possibility of an error in identification.

The chances of error are not great but they are definite. There is first the possibility that all cross-reacting agglutinins have not been absorbed from sera. An error due to inadequate absorption of Flexner W antiserum is reported in the present study. There is the possibility of reaction between absorbed serum and its specific antigen existing in a different species, as in the case of culture C-27, resulting, nevertheless, in an incorrect identification.

Just what the significance of an organism such as C-27 is in the scheme of the Enterobacteriaceae is uncertain; one would hesitate to classify this culture as *Sh. sonnei* from our present imperfect knowledge of the species and of organisms related to it antigenically. Wheeler and Stuart¹⁶ have described a motile paracolon strain with the complete somatic antigen of Sachs type Q771, and it seems possible that similar relationships between paracolon and *Shigella* organisms will be discovered in the future. Whether these related but atypical

organisms will be numerous enough to cause frequent errors in classification seems very doubtful. The paucity of reports in the literature would indicate that such cultures are few.

Should classification in the present study of ten motile, citrate-positive strains as *Sh. alkalescens* be considered as further error due to serologic methods? According to the present limits of the species, yes. It is evident, however, from the work of Stuart and co-workers²¹ that a new conception of the species may be realized and that classification according to the present limits may be changed.

Since *Sh. alkalescens* isolated from feces is not reported to the physician by our laboratory, any discussion of error in the classification of the motile, citrate-positive organisms is academic. It seems probable that many of these cultures have been, and are being, classified as *Sh. alkalescens* on the basis of conventional methods of identification. Motility is usually sluggish and is noticeable in semisolid medium only after twenty-four to thirty-six hours' incubation, while the reaction on citrate is slow, alkalinity appearing in three to five days.

In view of the results in the present study, it would appear that the chances of error in identifying the pathogenic *Shigella* by use of highly absorbed sera are slight. If we except from discussion the controversial issue of the limits to the species *Sh. alkalescens*, our rate of error was two out of 284 specimens, or approximately 0.7 per cent. When one considers methods of identification of several years ago, the results by the rapid method look very good indeed. How then would the mannitol-negative Boyd 103 strains have been classified? Would a report on either the Boyd 103 or the aerogenic Boyd 88 types have been made within a reasonable period of time in order that they might be of use to a physician?

A contrast of past and present methods in which present methods appear to advantage should not overlook the fact that the latter are subject to occasional errors. Therefore, at the completion of this study, our recommendation was as follows: A provisional report on the identity of *Shigella*-like organisms should be made, based on the outcome of the slide agglutination test. In our opinion the value of a rapid report to the physician justifies this procedure. Confirmatory motility and biochemical studies should continue to be made on each strain examined. This should be done both for confirmation of serologic results and to add to our knowledge of irregular biochemical reactions among the *Shigella*.

SUMMARY

1. Methods for production of highly absorbed *Shigella* antisera for use in the slide agglutination test are presented.

2. A total of 315 cultures which appeared dysentery-like on triple sugar agar was examined by slide agglutination technique with absorbed sera. Of these, 307 were accepted as *Shigella* on the basis of their reactions in absorbed sera. One of the 307, identified as *Sh. sonnei*, was found to be atypical in fermentation reactions and motile, yet it possessed the major antigen of *Sh. sonnei*.

Of thirty-two cultures identified serologically as *Sh. alkalescens*, ten were atypical in that they utilized citrate slowly and were motile. The remainder the 307 cultures were confirmed as *Shigella* by means of biochemical and tube agglutination tests.

3. One Sachs type Q771 strain was identified.

4. Rapid identification of two paradysentery strains could not be made because of "rough" phase in one culture and lack of specific antigen in the other.

5. Of five paracolon strains which reacted with polyvalent Flexner antiserum, four were eliminated as pathogens because of failure to react with monovalent serum; the fifth was incorrectly identified as Flexner W.

6. It was concluded that immediate reports on the identity of *Shigella* are justified when they are based on the rapid slide agglutination test, provided antisera used in the test have been highly absorbed. All identifications should be followed by tests of motility and biochemical studies.

THE SEROLOGIC RESPONSE IN MURINE TYPHUS AS MEASURED BY THE WEIL-FELIX, RICKETTSIAL COMPLEMENT FIXATION, AND RICKETTSIAL AGGLUTINATION REACTIONS

CARL T. NELSON, M.D.
NEW YORK, N. Y.

SINCE its introduction in 1916, the Weil-Felix test¹ has been a valuable aid in the diagnosis of rickettsial diseases in human beings. This reaction, based on the development of nonspecific agglutinins for the O or nonmotile variants of certain strains of *Proteus* X, has been widely used for diagnostic purposes because of its simplicity and accuracy in detecting rickettsial infections. In common with other nonspecific serologic reactions, however, the Weil-Felix test has limitations which, if not restricting its usefulness, often render its interpretation difficult. For example, it is now generally agreed that the test does not distinguish between typhus and the rickettsial diseases of the spotted fever group. This is of some importance in regions such as the Southern United States where murine typhus and Rocky Mountain spotted fever are both endemic. Moreover, the sera of normal persons who have never been exposed to rickettsial infection often contain low-titer agglutinins for *Proteus* X strains. Consequently it is usually not safe to draw diagnostic conclusions from the results of a single Weil-Felix test, even if the titer exceeds a level commonly regarded as significant. Another source of difficulty in assessing the significance of the Weil-Felix reaction may arise from the fact that agglutinins for *Proteus* X strains sometimes occur as a result of infection with *Proteus vulgaris* and *Proteus mirabilis*.²

With the development of improved methods for cultivating rickettsiae in relatively large amounts, it has become feasible to employ purified rickettsial suspensions as antigens in the serologic diagnosis of typhus and related diseases. When such antigens are used in complement fixation or agglutination tests they afford convenient means for diagnosing rickettsial infections. In addition, their greater specificity permits a differentiation between the various rickettsial diseases which give overlapping results with the Weil-Felix test.³⁻¹⁴ The antigens most commonly used at the present time are prepared by growing rickettsiae in the yolk sac of the developing chick¹⁵ or in the lungs of rodents.^{16, 17}

It is evident from data published thus far that there has been little occasion for studying the comparative effectiveness of suspensions of rickettsiae and *Proteus* OX strains in the early serologic diagnosis of murine typhus. As Felix has pointed out,¹⁸ murine typhus is essentially a sporadic disease with a relatively low fatality rate, and patients usually do not come under observation soon enough to permit an adequate investigation of the pattern of serologic

From the Department of Dermatology, College of Physicians and Surgeons, Columbia University.

Received for publication, Jan. 13, 1947.

response in the early stages of infection. The studies reported here were undertaken primarily to investigate the course of antibody development in patients with murine typhus by comparing the results of the Weil-Felix test with the specific rickettsial agglutination and complement fixation reactions. It was hoped that in this way it might be possible to evaluate more clearly the relative usefulness of the murine rickettsial agglutination and complement fixation tests in the early diagnosis of the disease.

METHODS AND MATERIALS

For the purposes of this study, multiple samples of blood serum were collected over a period of several weeks from patients with clinical evidence of typhus infection. In almost all instances these patients were residents of communities in the Southeastern United States where murine typhus is endemic. Efforts were made to obtain samples of serum at intervals of two to four days during the first three weeks of illness and at seven or eight days for the next five weeks. Thereafter, whenever possible, serum was collected once each month until a period of 150 days following the onset of illness had elapsed. In many cases, however, the patient could not be observed beyond the initial eight-week period. Although it was thus possible to obtain accurate data on the development of antibody levels, the persistence of titers in these cases could only be partially studied.

Sera collected in this manner were sent to a central laboratory where agglutination and complement fixation reactions with murine rickettsial antigens* as well as agglutination tests for Proteus strains OX 19, OX 2, and OX K were performed with each specimen. Sometimes complement fixation tests were also carried out with Rocky Mountain spotted fever rickettsial antigen. The serum specimens were tested as they were received at the central laboratory. In addition, the unused portions of successive sera from any one patient were stored at 4° C. and later retested simultaneously by each method. This was done to safeguard against possible variations in the reactivity of the antigenic suspensions. Only those patients who gave an accurate history regarding date of onset of symptoms and in whom it was possible to trace the progressive development of antibody titers during illness have been included in this report. Of the thirty-four nonfatal cases of murine typhus originally comprising this series, twenty-two could be studied sufficiently closely to yield accurate and comparable data.

The Proteus OX antigens employed in the Weil-Felix tests were alcohol-treated suspensions prepared and standardized according to Bridges' modification of Bien's method.^{19, 20} Prior to use, the concentrated suspensions were adjusted to a density approximating the McFarland nephelometer standard No. 3. For the agglutination tests, 0.5 c.c. amounts of suspension were added to 100 by 13 mm. round-bottomed tubes containing equal volumes of the patient's serum which had been made up in serial twofold dilutions ranging from 1:10 to 1:640. All tests were controlled with positive and negative sera. The tubes were centrifuged at 2,000 r.p.m. for seven minutes and then read macroscopically after shaking slightly to dislodge the particles from the bottom of each tube. The highest serum dilution showing any degree of agglutination was recorded as the titer. The reaction was arbitrarily considered to be positive when agglutination occurred in an initial serum dilution of 1:80 or more or when a fourfold increase in titer over a previous specimen had been observed.

Rickettsial agglutination tests were performed with antigens obtained from infected duck sacs of developing chick embryos.¹⁵ The rickettsial suspensions were prepared in the manner recommended by Fitzpatrick,¹⁴ using the ether-extraction method of purification. Such suspensions were found to be relatively stable, retaining their original specificity and reactivity for a period of at least six months when stored at refrigerator temperatures. Serum specimens for examination were diluted serially from 1:20 to 1:160 and tested by the slide agglutination technique previously described.¹⁴ Positive and negative control sera were

*The murine rickettsial antigens for agglutination tests were provided by the courtesy of Florence K. Pitt, M.D., & Dohme, Inc., Glenolden, Pa. The rickettsial antigens used in the complement fixation studies were supplied through the kindness of Dr. Ida A. B. Nation, Bethesda, Md.

included in each test. The slides were placed in the incubator at 40° C. for five hours and then stored at 4° C. overnight. Preliminary macroscopic readings were made after the slides had remained in the incubator for one and five hours, respectively. A final reading was made with the low-power objective of the microscope after overnight refrigeration. The test was recorded as positive only when complete agglutination was observed in an initial serum dilution of 1:40 or more. When agglutination occurred it usually was visible to the unaided eye within a period of one hour. In reading results the slide test presented none of the difficulties encountered by van Rooyen and associates¹² with rickettsial agglutination reactions in test tubes.

The antigens used for the complement fixation tests were also prepared from rickettsiae grown in the yolk sac of embryonated hen eggs.¹⁵ The rickettsial suspensions were made up and standardized by the method employed by Bengtson.²¹ Serum samples from each patient were inactivated at 56° C. for one-half hour and then diluted serially from 1:4 to 1:512. The technique of the complement fixation test was that described by Bengtson,²¹ using the customary reagent controls. Each day's tests were controlled also with positive and negative sera. The degrees of fixation were recorded as 4, 3, 2, and 1 plus, and trace. In this test a reaction of 3 or 4 plus in a serum dilution of 1:8 or higher was considered to be positive.

RESULTS

The results of the serologic studies in the twenty-two patients with murine typhus included in this series are summarized in Table I. Generally speaking, in most of these patients the Weil-Felix and rickettsial agglutination tests became positive earlier in the course of illness than did the rickettsial complement fixation reaction. Sometimes the Weil-Felix became positive slightly sooner than the rickettsial agglutination test; occasionally the reverse was true. For the most part, however, these reactions differed very little in this respect. In only one case was the rickettsial complement fixation test found positive before the other two.

TABLE I. EARLY SEROLOGIC RESPONSE, BY DAY OF DISEASE, IN TWENTY-TWO PATIENTS WITH MURINE TYPHUS

DAY OF DISEASE	NUMBER OF PATIENTS SHOWING A POSITIVE TITER BY		
	WEIL-FELIX	MURINE RICKETTSIAL AGGLUTINATION	MURINE RICKETTSIAL COMPLEMENT FIXATION
4	0	0	0
6	1	1	1
8	2	2	2
10	9	9	6
12	16	15	7
14	20	19	9
16	21	19	12
18	21	20	13
20	22	20	14
22	22	22	15

During the first week of illness all three tests seemed to be equally ineffective in establishing a serologic diagnosis of murine typhus. In the second week of illness the Weil-Felix and rickettsial agglutination tests were usually positive and were clearly superior to the complement fixation reaction in detecting the disease. Even three weeks after onset, when the two agglutination tests were positive in all instances, the complement fixation reaction was still negative in nearly one-third of the cases. In one patient the presence of complement-fixing

antibody was not demonstrated until six weeks after illness began. Further data, comparing the per cent of positive Weil-Felix, rickettsial agglutination, and rickettsial complement fixation reactors by day of disease, are shown in Fig. 1.

These findings suggest that the Weil-Felix and rickettsial agglutination tests are more valuable than the rickettsial complement fixation reaction in the early serologic diagnosis of murine typhus. The rickettsial agglutination reaction, in turn, is superior to the Weil-Felix test in that it is more specific and permits a differentiation to be made between the murine and spotted fever types of infection. In view of this one may conclude that the rickettsial slide agglutination test, as performed in this work, is a superior serologic method for detecting murine typhus in the early stages of the disease.

FIG. 1.—Per cent of positive Weil-Felix, rickettsial agglutination, and rickettsial complement fixation reactors, by day of disease, in twenty-two cases of murine typhus.

Additional information gained in the course of these studies indicates that once the rickettsial complement fixation reaction becomes positive it remains so for a relatively long period of time. In this respect it does not appear to differ significantly from the rickettsial agglutination test. Although the persistence of antibody levels in these patients could not be studied completely, it seems clear that the Weil-Felix is the most evanescent of the three reactions and frequently becomes negative eight to twelve weeks after the onset of symptoms.

DISCUSSION

According to Felix,^{18, 22} the majority of cases of louse-borne typhus and many cases of murine typhus can be diagnosed by the OX 19 reaction during the first week of illness. This has been denied by other investigators^{12, 23} who

point out that significant agglutinin titers for rickettsiae and *Proteus* OX 19 usually are not attained by such patients until early in the second week of disease. In so far as murine typhus is concerned, the data presented here indicate that in most cases the disease cannot be diagnosed by serologic methods until after the eighth day of illness.

From time to time in the past, certain workers have postulated that the pattern of agglutinin formation in cases of typhus is related to the clinical course of the disease.^{18, 24} Generally speaking, patients with cases of moderate severity are said to respond with high titers, while those with most severe cases, including those who succumb to the infection, have very low titers. In this small series of patients, little or no relationship between the severity of illness and the magnitude of antibody response was found. While this work was in progress it was possible to observe three patients with uncomplicated murine typhus which terminated fatally. In each of these the agglutinin and complement-fixing titers reached high levels prior to death. Although the number of patients studied does not permit one to draw definite conclusions, it seems that the antibody levels attained in murine typhus are subject to wide individual variations and that if an inverse relationship exists between clinical severity and the height of antibody response it must be a tenuous one.

The specificity of rickettsial agglutination and complement fixation reactions already has been demonstrated conclusively by several investigators.^{4, 8, 10, 12-14, 17, 25} In the absence of previous rickettsial infection or vaccination, sera from normal persons and individuals suffering from nonrelated febrile illnesses almost never contain antibodies for rickettsial antigens. This was amply confirmed during the course of these studies. On the other hand, some degree of cross agglutination and complement fixation with murine, classic, and spotted fever antigens may be expected to occur in sera from patients with typhus and spotted fever. When the rickettsial suspensions are properly standardized, however, the titer for the infecting strain is usually significantly higher than the heterologous antibody levels. Thus a serologic differentiation may be made between diseases of the typhus and spotted fever groups by means of the agglutination and complement fixation tests.

Plotz and associates²⁶ have recently indicated that the rickettsial agglutination reaction is less effective than the complement fixation test in differentiating between typhus and Rocky Mountain spotted fever. These investigators, using an unspecified macroscopic agglutination technique, found that the sera from thirteen patients with Rocky Mountain spotted fever gave considerable agglutination with murine and classic rickettsiae, whereas no cross reactions for the typhus antigens occurred in the rickettsial complement fixation test. During the present study there was an opportunity to observe the serologic response in three patients with Rocky Mountain spotted fever. In two of these no cross agglutination with murine typhus antigen was noted in the slide agglutination test. In the third patient partial agglutination in low titer (1:40) occurred with murine rickettsiae, but this titer remained stationary throughout the disease. Sera from all three patients, however, gave slight to moderate cross reactions with murine

rickettsial suspensions in the complement fixation test. While it is obviously impossible to generalize from scattered observations of this sort, such findings tend to reaffirm the value of the slide agglutination test used in these studies for the differentiation of rickettsial diseases. Moreover, from a clinical standpoint, these results emphasize that the more elaborate complement fixation reaction probably possesses no differential diagnostic virtues which are not also shared by the simple slide agglutination test.

SUMMARY

1. An investigation of the serologic response in twenty-two cases of murine typhus has shown that the Weil-Felix and rickettsial agglutination reactions usually become positive earlier than the rickettsial complement fixation test in this disease.

2. Because of its specificity and sensitivity, the rickettsial slide agglutination test employed in these studies is particularly useful in the early serologic diagnosis of murine typhus.

3. In so far as the detection of murine typhus in its acute stages in man is concerned, the relatively simple rickettsial slide agglutination test is fully as effective as the more elaborate complement fixation reaction.

Grateful acknowledgment is made to Frances S. Friedman, M. Edwena Parrish, and Lucia L. Smith, for their technical assistance in this work.

INFLUENZA B IN NEEDHAM, MASSACHUSETTS, DECEMBER, 1945

SEROLOGIC STUDIES IN CASES AND IN FAMILY CONTACTS

MAXWELL FINLAND, MILDRED W. BARNES, MANSON MEADS, EDWIN M. ORY, AND
A. DANIEL RUBENSTEIN
BOSTON, MASS.

ATTENTION was first called to the possibility of a sizable outbreak of influenza in Needham, Mass., by an abrupt rise in the number of absentees in the Junior High School during the second week of December, 1945. Through the cooperation of the local school and health authorities and of many of the residents of the community, an opportunity was afforded to study certain aspects of this outbreak. The present paper includes a report of serologic studies made in a limited number of cases and family contacts. The epidemiologic observations are reported elsewhere.¹

MATERIALS AND METHODS

Collection of Materials.—Visits were made to the Junior High School and to the homes of a number of pupils who were acutely ill with influenza between Dec. 13 and 16. Throat washings were obtained at this time from several individuals who were still acutely ill with the symptoms of influenza and with a fever of 101° F. or higher. At the same time samples of venous blood for serologic studies were obtained aseptically from individuals with acute influenza and from members of their families, including both persons with influenza and apparently healthy contacts. Clinical histories were also obtained at this time. A second visit was made to each of the same families between Dec. 29, 1945, and Jan. 2, 1946. At that time blood was again drawn from patients and contacts and a history was obtained of any illnesses that may have occurred during the intervening period. As far as could be ascertained, none of the patients or contacts had received inoculations of influenza vaccines.

Clinical Findings.—The clinical features of the cases of influenza were quite characteristic and consisted of fever (100 to 104° F.), prostration, eyeball pain, generalized aching, some cough, and occasionally a mild sore throat. There was usually slight conjunctival injection and supraorbital edema. A few scattered râles were heard in the lungs of some of those individuals who were examined. The severity of the illness was rated as 1 to 3 plus, according to the degree of prostration, height and duration of fever, and the severity of the systemic symptoms. Four adult contacts of patients with influenza had slight fever and predominantly gastrointestinal symptoms which had been called "in-

testinal flu." There were four other contacts, one a cafeteria worker at the school and three parents of individuals with influenza, who were afebrile and had symptoms characteristic of a common cold, with coryza predominating.

Antigens.—The antigens used in the serologic tests included the PR8 strain of influenza A, the Lee strain of influenza B, strains WC and MF isolated from throat washings obtained on Dec. 14 from patients with acute influenza among the Thorndike Laboratory staff who had no contact with the Needham cases, and strain MB isolated from throat washings on the first day of illness from one of the patients in the Needham outbreak (patient 6 in Table I). The PR8 and Lee viruses were originally obtained from Dr. Thomas Francis, Jr., and the others were isolated by amniotic inoculation and passage and were subsequently transferred through more than twenty allantoic passages. Each was concentrated from a pooled harvest of allantoic fluid by elution from the embryonic erythrocytes according to the method of Francis and Salk² and kept in a CO₂ icebox at about -70° Centigrade. Details of the isolations of influenza strains during this epidemic will be presented elsewhere.

Serologic Tests.—The sera were kept in an electric refrigerator (deep freeze) at -20° C. in rubber stoppered Pyrex tubes and rapidly thawed each time before any was withdrawn for the tests. All serologic tests were carried out in two-fold dilutions of serum and saline beginning with 1:4. Paired sera from each person always were tested at the same time, usually with two or more viruses. A majority of the tests were repeated on two or more separate occasions. At least on one occasion in most cases, dilutions of the sera made up at one time were run simultaneously with three or four of the viruses in both agglutinin inhibition and complement fixation tests. The agglutinin inhibition tests were set up essentially as described by Hirst.³ Chicken blood for these tests was obtained from a local slaughterhouse and the blood from three or more chickens was pooled each time. The details of the complement fixation test were similar to those described by Enders and associates⁴ for the mumps virus. Titers were recorded as the reciprocal of the greatest initial dilution of serum before adding other reagents. The end point in the Hirst test was read at the dilution in which erythrocyte agglutination was completely absent (0) or estimated up to 25 per cent (+). In the latter event the titer was arbitrarily reduced by one-half of the value of the preceding interval. (Example: Complete inhibition in 1:64 and plus agglutination in 1:128; titer is 128 less 32 or 96.) In the complement fixation test the end point was graded 1 to 4 plus, the former representing an estimated 75 per cent hemolysis and the latter complete fixation, that is, no hemolysis. The 1, 2, and 3 plus readings were reduced $\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$, respectively, of the value of the preceding interval. Examples: No hemolysis (4 plus) in 1:64 and complete hemolysis (0) in 1:128; titer is 64. No hemolysis (4 plus) in 1:64 estimated 25 per cent hemolysis (3 plus) in 1:128, and complete hemolysis (0) in 1:256; titer is 128 less $\frac{1}{4}$ of 64 or 112.) The titers of serum which showed no antibody in the initial dilution (1:4) were arbitrarily given the value of 2.

RESULTS

Virus Isolations.—Attempts to isolate a virus from the throat washings obtained from patients with acute clinical influenza in the Needham outbreak were unsuccessful in most instances. The washings had been kept chilled during transit and stored in sealed Pyrex tubes in a CO₂ icebox as soon as they reached the laboratory. Unfiltered washings with 150 to 500 units of penicillin added were inoculated. Various combinations of amniotic and allantoic passages in eggs with or without mouse passages were used. In some instances evidence suggesting the possible presence of influenza virus was obtained in the course of some of the early passages in the embryonated eggs by the hemagglutination of the embryonic erythrocytes, but subsequent passages failed to establish the presence of a virus in most of them. Successful isolations of influenza viruses from this season's cases had been obtained only from the three cases mentioned at the time the present studies were being carried out. The three strains were readily identified serologically as type B influenza and were used in the present studies for comparison with the Lee strain.

Cases Studied.—Included in the serologic study are eleven families and two isolated cases, a total of thirty-nine persons. In each family there was at least one with typical symptoms of clinical influenza of moderate severity and from one to four others, either patients or healthy family contacts, from whom sera for serologic studies were obtained at the same time. The two isolated cases included a pupil and a cafeteria worker at the Junior High School. The influenza antibody titers in each of these individuals are shown in Table I, together with the date of onset and a rough estimate of severity in the cases of clinical influenza. Each titer represents the average for all the tests done with the virus and serum concerned. Patients in whom the symptoms were essentially those of a mild common cold with little or no fever and with coryza as the only significant feature are listed under Severity as *C*; those with low grade fever and diarrhea as the outstanding manifestation are designated as *D* in the same column in Table I.

Serologic Results in Typical Cases of Influenza.—

Influenza A Antibodies: There were nineteen characteristic cases of clinical influenza, and the symptoms in each instance began between Dec. 9 and 15. There were three such cases in each of two families, two in each of three families, and six that were the only typical cases among the persons studied in their families; there was one isolated case of clinical influenza with no family contacts included in the study. In none of these nineteen cases was there any significant rise in titer of antibodies against the PRS strain of influenza A by either the agglutinin inhibition or complement fixation test.

The level of the antibody titers obtained with the PRS strain by the tests employed are worth noting. A titer of 32 or higher was obtained in only one of the sera (the convalescent serum of Patient 7) by the complement fixation test, whereas titers ranging from 64 to 384 were obtained by the agglutinin inhibition test in both of the sera from six individuals and in the acute serum of a seventh person. The low titers were not the result of poor sensitivity of the

strain, since high titers and sharp rises in titers to high levels were obtained with the same antigen by both tests in unvaccinated individuals and in several patients with influenza A which occurred late in January, 1946.⁵

Influenza B Antibodies: Significant rises in titer of influenza B antibodies were demonstrated with two or more of the four strains used in fourteen of these cases and the rises were quite marked in most instances. Two additional cases showed significantly high titers but no rises were demonstrated. In Patient 14 the initial blood was obtained on the seventh day after the onset of symptoms, and while no significant rise in titer of antibodies for any of the type B strains was demonstrated, the titers of these antibodies initially were comparable with or higher than the titers obtained with the convalescent phase sera in several other cases in which a fourfold or greater rise had been demonstrated. This suggests the likelihood that a maximum titer already had been reached in that case at the time when the initial blood was drawn. Twin siblings of this case each showed a marked rise in influenza B antibodies but the onset of their symptoms occurred five and six days later, respectively, and their initial titers were much lower. In Patient 13 only a single sample of blood was obtained fourteen days after the onset of symptoms and in that serum high titers of antibodies against all of the influenza B strains were obtained by both tests. These titers were comparable with the convalescent titers in cases exhibiting a marked rise, indicating that in this case too the high titers were probably the result of recent infection with influenza B.

Negative Serologic Responses: The three remaining typical cases of clinical influenza (Patients 24 to 26) showed no significant titers or rises in titers of influenza B antibodies. The patients were all members of Family W and were the only persons studied in that family. The initial sera in these cases were obtained between the third and sixth days after the onset of clinical influenza. The illness in these patients occurred during the peak of the outbreak and was considered to be of average severity in two and mild in the third. The antibody titers obtained with the Lee strain and with two or all three of the recently isolated strains of influenza B were low in almost every instance. The initial titers of antibodies for PR8 were moderately high in the agglutinin inhibition tests in two of these cases but the complement-fixing antibodies were of low titer for this strain in both instances. Both tests gave low titers with the PR8 strain in the third case.

Strain Differences: A few details concerning the influenza B antibodies in the typical cases of clinical influenza are worth noting. In every case in which a rise in titer of antibodies was demonstrated with the Lee strain, comparable rises in titer of antibodies also were demonstrated with the recently isolated strains. There were three cases, however, in which tests with the Lee strain failed to bring out a rise in titer of influenza B antibodies by either agglutinin inhibition or complement fixation or by both tests when such a rise was demonstrated with the recently isolated strains. The original titers of influenza B antibodies in these cases were all low. The sera in Patient 18 showed no rise in titer of agglutinin inhibiting antibodies for the Lee virus when tested on

three separate occasions; however, a significant rise in titer was demonstrated by the complement fixation tests simultaneously with the same virus, and dilutions of serum made up at the same time. Tests done with the WC and MF strains also showed two- to fourfold rises in titer in this case, but the results with the epidemic strain MB were similar to those obtained with the Lee strain. The sera in Patients 21 and 27 showed no rise in titer of antibodies for the Lee strain by either the agglutinin inhibition or complement fixation tests done on four separate occasions, but they showed appreciable rises by both tests done with the WC and MF strains. In neither of these two was any significant rise elicited with the MB strain either. There were no gross discrepancies between the results obtained in the same sera with the WC and MF strains by either agglutination inhibition and complement fixation tests, and the differences that were noted were quantitative and were usually only slight. The findings in these three cases suggest that the WC and MF strains are more closely related to each other than to the Lee and MB strains and also that the MB strain is more nearly like the Lee strain than are the other two recently isolated strains. Such a deduction, however, requires substantiation from more detailed antigenic studies before it is acceptable.

Cases Resembling Common Cold.—The four patients in whom fever was absent and the symptoms were considered to be those of the common cold are of interest. Three of them (Patients 9, 22, and 28) were mothers of families in which at least one child had clinical influenza associated with a significant rise in titer of antibodies for the type B viruses. The fourth (Patient 38) was an adult cafeteria worker at the Junior High School. The onset of symptoms in Patient 22 occurred early in November, 1945, but in the others the illness began at about the same time as in those patients with the typical course of clinical influenza. The sera of each were tested several times with the PR8 and Lee viruses and at least once with each of the three recently isolated strains. None of these four cases showed significantly elevated titers or rises in titers of antibodies for any of the viruses used. The initial titers, in fact, were similar to those obtained with the same viruses in the acute phase sera of cases of clinical influenza showing typical rises with the strains of influenza B.

Patients With Intestinal Manifestations.—The four patients in whom the symptoms were predominantly gastrointestinal are also of interest because of the possible relation of influenza virus infection to these symptoms. Each of these patients was the father of a family in which there was at least one child with clinical influenza in whom a rise in titer of antibodies for at least two of the strains of type B influenza virus was demonstrated. In none of these four was a significant rise in titer of antibodies demonstrated for any of the viruses used. The data on these four patients, however, are not so clear as in the group with the symptoms of colds. In one of them, Patient 29, there was only a single specimen of serum obtained eighteen days after the onset of symptoms and all of the titers were low. In each of two others, Patients 12 and 32, the initial blood was obtained ten days after the onset of fever and diarrhea. In the latter two the titers of antibodies for some of the type B

strains, particularly the titers obtained by the complement fixation test, were higher than in most of the acute phase sera of patients in whom a significant rise was later demonstrated. Finally, in the fourth, Patient 19, the symptoms began ten days after the initial specimen was obtained and only four days before the second sample of blood was drawn.

Household Contacts.—The results of the tests on the sera of the healthy household contacts of those patients in whom a rise in titer of influenza B antibodies was demonstrated are also of interest since little information is available concerning the influenza antibody response under just these conditions. There were twelve such household contacts in whom pairs of blood samples were obtained at the same time, as in the patients with clinical influenza. Four of the twelve were in Family F and two in Family N, and there was one in each of six other families. Unfortunately only two of these contacts were children. The rest were adults; almost all of them were parents of the patients, presumably being in fairly close contact with them. That was particularly true of mothers who in each instance nursed their children through the illness at home.

Half of these healthy contacts showed no rise in titer of antibodies against any of the four type B strains by either of the tests used. There were two individuals, Patients 2 and 5, both in Family F, in whose sera a fourfold rise in titer was elicited against the epidemic strain MB by the complement fixation test. In both of them the agglutinin inhibition test showed a twofold rise with the same virus, and similar slight rises which are not ordinarily considered to be significant also were noted in the complement fixation tests with the remaining type B strains. Four other contacts (Patients 3, 8, 11 and 17) each showed a twofold rise in titer of antibodies against one or more of the type B strains by either or both tests. There were only two instances (Patients 17 and 34) in which a twofold rise in titer was elicited with the PR8 strain by one or the other of the tests. Except for the elevated titers of agglutinin inhibition with PR8 mentioned earlier, the titers in the initial samples in all of these healthy contacts were essentially similar to those observed in the acute phase sera of the patients with clinical influenza in whom significant rises in influenza B antibodies were elicited.

Comparison of Agglutinin Inhibition and Complement Fixation Tests.—Except as already noted, the levels of the antibody titers obtained in any single specimen of serum by inhibition of hemagglutination and by complement fixation of the same virus usually corresponded fairly closely considering the limitations of the methods. The greatest and most frequent discrepancies were observed in the titers obtained with the PR8 strain: Several sera yielded high titers by inhibition of agglutination with this strain, but significantly high titers with the complement fixation tests were not observed. Except as noted earlier, the two tests also gave quite comparable titers in the same sera with each of the four strains of influenza B virus. In a few sera slightly higher titers with these viruses were obtained by complement fixation than by the inhibition of hemagglutination.

Tests With the BON Strain of Influenza B.—After all of these studies were completed, Dr. John F. Enders suggested that serologic tests with the BON strain also might be of interest. This strain was isolated by chick-embryo inoculation in Australia in 1943 by Beveridge and associates,⁶ who showed it to be serologically related to, but readily distinguishable from, the Lee strain of influenza B. The results of the tests done on fifteen pairs of sera that were still available are shown in Table II.

*Ac, Anticomplementary in lower dilutions.

Of particular interest is the demonstration of definite rises in antibody titers against the BON strain in Patient 21. In this respect the BON strain was similar to the WC and MF strains and unlike the Lee and MB strains. Tests were also done on the sera of six other patients with influenza including those from four (Patients 1, 7, 10, and 37) in whom definite rises in antibody titers had been elicited with the other type B strains and those from two others (Patients 25 and 26) in whom rises in antibody titers were not demonstrated. Similar results were obtained with the BON strain in each instance. The remaining eight persons whose sera were tested included two who were considered to have "colds" (Patients 9 and 22), one who had diarrhea (Patient 12), and five healthy contacts. The results obtained with the BON strain in the sera of these individuals also were essentially the same as those obtained with the other type B strains.

DISCUSSION

Among the present cases the serologic evidence clearly indicates that influenza B was the predominant if not the only virus implicated in the influenza outbreak at Needham. Evidence suggesting that probably only type B influenza occurred during the same period in Boston has also been obtained serologically and from the only successful isolation of virus from patients with acute influenza. Similar experiences were also reported from other localities at the same time.^{7, 8} In a boys' school located several miles north of Boston, however,

an outbreak occurred during January, 1946, which was proved serologically to be due to influenza A, and no cases of influenza B infection were identified among students at that school.⁹ Furthermore, among sporadic cases of clinical influenza which occurred in Boston a few weeks after the peak of epidemic prevalence of influenza B, several were identified serologically as influenza A. Included among the latter were persons who had previously suffered an illness, which was proved serologically to be influenza B during the epidemic, and were thus instances of consecutive infections with two distinct viruses.⁵ Isolation of influenza A virus during December, 1945, was reported from Illinois,¹⁰ and both influenza A and B infections were demonstrated in Australia earlier that year.¹¹

The findings in Family W in which three seemingly typical cases of clinical influenza yielded negative serologic results have not been explained. These cases occurred during the height of the epidemic and one of them was in a pupil at the Junior High School. The cases may have been somewhat less severe than most of the others that were studied. Since a virus was not isolated from any of these cases, the possibility cannot be excluded that they had responded in a highly specific manner to their own strain but not to the related strains of influenza B virus used in this study. On the other hand, they may represent infections with a totally different virus or, what seems more likely, failures to respond with a rise in antibodies to typical strains, as Magill and Sugg¹² have shown in some cases of influenza A infection.

During the present outbreak in Needham, Mass., as well as in Boston and elsewhere, there were many patients with predominantly gastrointestinal symptoms interspersed among those with epidemic influenza. Some of these patients with so-called "intestinal flu" also had fever and other systemic symptoms such as malaise, headache, and prostration, which made it difficult to exclude the diagnosis of clinical influenza. The four cases included in this study and several others which were studied in Boston during the same time all failed to yield any definite serologic evidence of influenza by the development of antibodies to any of the viruses used in this study, in spite of close association of most of them with proved cases of influenza B.

Cases of common cold and other undifferentiated respiratory infections are always prevalent during the season when influenza outbreaks occur, and it is not always possible to distinguish isolated cases from those of influenza on purely clinical grounds. In the present study the four cases which clinically were considered to be common colds all failed to respond to their infection with a rise in antibodies to any of the viruses used, and the same was true of several additional cases studied in this laboratory during the same period. There were other cases, however, in which clinical differentiation was difficult and some of them proved serologically to be influenza B. The number of individuals of this type and of those with intestinal manifestations was too small to warrant any final deductions as to their relation to the prevalent influenza virus infections.

The same also may be said of the observations made on influenza antibodies in the healthy family contacts of patients with proved influenza B. The

present studies reveal no clear evidence of inapparent infection in these individuals, unless the slight rises in antibody titers can be interpreted in that way. Nor was any evidence found to indicate that the healthy contacts were protected by virtue of an adequate antibody content in their blood. These negative results may be a reflection of a type of resistance to infection among these contacts which could not be measured serologically with the available viruses or they may indicate an inapparent infection with an inadequate antibody response or with a strain of virus having low infectivity or low antigenicity in these individuals. Inapparent infections with influenza A as manifested by the development of antibodies in the absence of symptoms have been reported,¹³⁻¹⁶ and influenza A virus has been isolated from apparently normal human contacts during an epidemic of influenza.¹⁶ Serologic tests on contacts of patients with influenza B infections in an institutional outbreak in 1939 indicated an incidence of subclinical infection equal to that of clinical infections.¹⁷

Evidence was obtained which suggested antigenic differences between the recently isolated strains and the Lee strain of influenza B. Some cases which failed to show a rise to the latter reacted with a characteristic antibody response to some of the former. On the basis of the very meager evidence on Patient 21, together with the results on Patients 18 and 27, the strain MB from the Needham case appears to be antigenically similar to the Lee virus, whereas the strains WC and MF are more like the BON strain. There also was suggestive evidence of discrepancies between the antibody titers obtained by inhibition of hemagglutination and by complement fixation with the same viruses. The discrepancies were more frequent and more consistent (that is, the inhibition titers were always much higher) with the PR8 strain than with the B strains. With the latter viruses some titers were higher with one test and some with the other. These may be related in some way to the differences in antigenic components of the viruses as described by Wiener and associates.¹⁸

SUMMARY AND CONCLUSIONS

1. Serologic studies were carried out in cases and in family contacts during an outbreak of influenza which occurred in Needham, Mass., during mid-December, 1945.
2. The typical cases of influenza, with three exceptions, yielded evidence of infection with influenza B by a rise in titer of antibodies. The three exceptions were all individuals in the same family.
3. Some of the cases showed a rise in antibodies when tested with two strains of influenza B recently isolated from cases in Boston but failed to show such a rise in the same sera when tested with the Lee strain of influenza B and with a strain isolated from one of the cases in Needham.
4. Among the family contacts of the serologically proved cases of influenza B there were four who had symptoms which were more like those of the common cold (mostly coryza without fever) and four others who had low grade fever and predominantly gastrointestinal symptoms. No serologic evidence of influenza virus infection was obtained in any of these individuals.

5. Healthy family contacts of the proved cases of influenza B also failed to show significant rises in antibody titers in their sera for any of the strains of influenza B virus used or for the PR8 strain of influenza A, but slight rises were elicited in some of them.

6. There were some discrepancies between the titers obtained in the same sera by inhibition of hemagglutination and by complement fixation test with the same virus. These discrepancies were more frequent with the PR8 strain, and when they occurred, the agglutinin inhibition test with this virus gave the higher titers. Some sera gave higher titers in this test with the B strains, but more gave higher titers with the complement fixation test.

THE EFFECT OF ANTIHISTAMINE DRUGS UPON SERUM-INDUCED MYOCARDITIS IN RABBITS

FRANKLIN A. KYSER, M.D., JOHN C. MCCARTER, M.D., AND JAMES STENGLE, M.D.
EVANSTON, ILL.

THE recent work of Rich and Gregory⁷ upon the role of hypersensitivity in rheumatic fever once again has focused attention upon a problem that has perplexed investigators for many years. Before discussing the work to be presented in this paper, it would seem advisable to review briefly some of the pertinent contributions on this subject.

Swift¹⁰ pointed out in a classic paper in which a complete review of the literature is given that the histologic picture of rheumatic fever may vary in different individuals, just as does the clinical picture, and that a patient who has had a rheumatic infection reacts more profoundly to the etiologic agent than does the individual who never has had rheumatic fever. He believes that this reaction is the result of a state of hypersensitivity. In a later communication Swift and co-workers¹¹ describe attempts to diminish the state of hypersensitiveness in rheumatic fever by giving repeated injections of a specific streptococcal vaccine. These workers believe that "if by this means of immunization the natural resistance of the tissues can be so enhanced that subsequent infection is met and tolerated with only a minimum of injury, the method will have been justified."

Gross and associates⁴ attempted to produce rheumatic-like lesions by injecting various strains of streptococci isolated from patients with rheumatic fever into experimental animals. Their criteria for a diagnosis of experimental rheumatic fever were: (1) the Aschoff body, (2) nonbacterial pericarditis, and (3) nonbacterial verrucous endocarditis. These authors were unable to meet the criteria in their experimental lesions, and they stated that other workers had been too lax in their interpretation of results. The present paper also points out that perivascular accumulations occur in the normal rabbit heart.

Clark and Kaplan² presented a summary of the evidence that anaphylactic vascular lesions induced in animals are very similar to the histologic changes occurring spontaneously in rheumatic fever, periarteritis nodosa, and scarlet fever. The authors present the pathologic findings in two cases of serum sickness and suggest that the lesions are the result of a hypersensitive state. Rich⁶ in a later paper again emphasized the role of anaphylactic hypersensitivity in patients who developed periarteritis nodosa following serum sickness.

In 1943 Rich and Gregory⁵ published evidence that lesions resembling periarteritis nodosa can result from injections of sterile unpreserved horse serum into rabbits. In the same year work was presented in which lesions similar to rheumatic carditis were produced in rabbits by a similar method.

From the Evanston Hospital, and the Departments of Medicine and Pathology, Northwestern University Medical School
Received for publication, Jan. 30, 1947.

Rich and Gregory⁷ state that "the valvular and myoeardial lesions which in their situation and basic characteristics conform so closely with those of rheumatic carditis that we believe they may provide a fair measure of support for the view that the specific rheumatic lesions may themselves be manifestations of an anaphylactic hypersensitive reaction." In this study eleven out of thirty-six rabbits developed rheumatic-like changes in the hearts. Rich and Gregory⁷ describe in detail the characteristic cardiac lesions of rheumatic carditis and discuss ten major points as evidence that rheumatic lesions are hypersensitive in character. The histologic changes which were produced by Rich and Gregory were: (1) lesions similar to Aschoff bodies with the presence of Anitschkow myocytes or cells similar to them, (2) focal accumulations of mononuclear cells and large basophilic cells similar to those that characterize the Aschoff body, and (3) nonspecific lesions consisting of edema, round cells, and polymorphonuclear leucocytes.

Fox and Jones⁸ repeated the work of Rich and Gregory and produced lesions similar to those of rheumatic carditis in twenty out of thirty rabbits. Robinson⁹ was unable to produce cardiac lesions in ten rabbits injected with sterile horse serum; however, it must be noted that the animals in this work were killed in seven to twenty days, which probably accounts for the result obtained.

In 1945 Aikawa¹ summarized very completely the literature on this entire subject and discussed many papers which have not been mentioned in this presentation.

PRESENT STUDY

In the work herein reported the primary consideration has been to produce lesions in the rabbit heart according to the method of Rich and Gregory⁸ and to note the effect of certain drugs upon the development of such lesions. No claim is made that the lesions are characteristic of rheumatic fever, although in many instances the changes produced bear a striking resemblance to the histologic picture of acute rheumatic carditis.

Thirty-nine young adult rabbits were used in our study. Of this group, nine animals died before the experiment was completed and the hearts of three of these nine were examined. However, our results are compiled only on those animals that lived throughout the entire study.

Sterile unpreserved horse serum was injected intravenously into rabbits according to the method of Rich and Gregory.⁸ In one group of animals serum with preservative was used, and this fact will be emphasized in the results presented herein.

The animals were divided into the following groups:

Group I. Twelve rabbits received serum alone.

Group II. Nine rabbits received serum plus 2 mg. of beta dimethylaminoethyl benzhydryl ether hydrochloride (benadryl) two times daily subcutaneously throughout the duration of the experiment.

Group III. Six rabbits received serum plus 10 mg. of benadryl per kilogram of body weight two times daily subcutaneously throughout the duration of the experiment.

Group IV. Nine animals received serum plus an experimental drug* which has been shown to have antihistamine qualities, as measured by the Loew histamine spray test and by giving protection against anaphylaxis in guinea pigs. Throughout the remainder of this paper the drug will be named No. 1627. The dosage was 3 mg. per kilogram two times daily subcutaneously.

Group V. Three rabbits received serum alone and were used as controls for Group IV. In Group IV and V the third, or shocking, dose of serum contained a small amount of preservative, the significance of which is not known. For this reason the series of controls is kept in a separate group.

RESULTS

The results are summarized in Tables I to V.

Group I. Serum alone. Ten rabbits developed marked cardiac lesions. One rabbit developed moderate lesions. These consisted of the following types of changes:

1. Pericapillary and periarteriolar collections of lymphocytes and monocytes with occasional polymorphonuclear leucocytes. In many sections small areas of necrosis were found adjacent to blood vessels, surrounded with mononuclear cells, which resembled the Aschoff body. In many vessels the entire wall of the vessel was infiltrated with cells. Endothelial proliferation was marked, and in some sections hyalinization of the vessel wall was evident. Periarteriolar proliferations of fibroblasts frequently were present.

2. Scattered areas of hyalinization of muscle fibers.

3. Loose infiltrations with small round cells scattered between muscle fibers.

4. Occasional areas of vacuolar degeneration of fibers.

These changes are demonstrated in Figs. 1 to 6.

Group II. Serum plus benadryl. Four rabbits revealed no lesions or minimal changes. Two rabbits developed moderate cardiac lesions. In this

TABLE I. GROUP I SERUM ALONE

645	2,450	29	Moderate
647	1,700	29	Marked

*Developed by G. D. Searle & Company, Chicago, Ill.

group the absence of perivascular changes was striking. Only in an occasional section were lesions found adjacent to blood vessels. No lesions resembling Aschoff bodies were seen. There were present, scattered between muscle fibers, small infiltrations of mononuclear cells and lymphocytes. Occasional areas of vacuolar degeneration were seen. Throughout all sections the lesions were very much less marked than those of Group I.

 Fig. 2.—Periarterial infiltration with lymphocytes and monocytes ($\times 200$).

Group III. Serum plus 10 mg. of benadryl per kilogram twice daily. Three rabbits showed no cardiac changes. Two animals revealed the presence of only an occasional perivascular infiltration, and these lesions were classified as minimal. One rabbit did develop a moderate number of lesions but not nearly as marked as in the control group.

Group IV. Serum plus drug No. 1627. Eight rabbits developed no lesions or only very slight changes. One rabbit developed moderate changes. Only occasional perivascular lesions were present. Nothing resembling an Aschoff body was seen. It must be pointed out that in this group and in Group V the third dose of serum contained a small amount of preservative.

Group V. Serum alone to act as controls for Group IV. Two rabbits developed marked cardiac changes and one animal showed only slight changes.

DISCUSSION

From the literature reviewed and from the results herein reported, one is justified in stating that cardiac lesions may be produced in rabbits by the proper intravenous administration of horse serum. Gross and co-workers⁴ state that perivascular infiltrations may occur in normal rabbits. In the present study

Fig. 3.

Fig. 3.—Lesion simulating an Aschoff body adjacent to arteriole ($\times 450$).

Fig. 4.

Fig. 4.—Lesion simulating an Aschoff body adjacent to arteriole ($\times 540$).

only a very occasional perivascular lesion was found in the animals that received benadryl and drug No. 1627. The control animals showed rather extensive lesions. We therefore feel that even if perivascular lesions do occasionally occur in the normal rabbit heart this fact does not alter the results of this experiment. Miller⁵ has stated that 60 per cent of normal rabbit hearts will show cellular infiltrations between the muscle fibers. This may be true and, if so, will in no way change the evaluation of the results of this work, since most of our emphasis has been placed on the presence of vascular and perivascular lesions.

The similarity of the changes found in our control groups to the cardiac lesions of acute rheumatic carditis is striking. Since two antihistamine drugs have been shown to impede the development of these cardiac lesions in rabbits, it would seem advisable for further experiments to be carried out in an effort to determine the relationship of rheumatic fever to a hypersensitive state.

Fig. 5.

Fig. 6.

Fig. 5.—Infiltration around and into wall of artery by lymphocytes, monocytes, and eosinophiles; organizing thrombus is present in lumen of vessel ($\times 540$).

Fig. 6.—Periarteriolar infiltration ($\times 500$).

SUMMARY

Evidence is presented that benadryl and drug No. 1627, two antihistamine drugs, will impede the development of serum-induced myocardial lesions in rabbits. A brief review of the pertinent literature is included.

CONCLUSIONS

1. Myocardial lesions may be produced in rabbits by the injection of sterile horse serum according to the method of Rich and Gregory.
2. Benadryl and drug No. 1627 are effective in impeding the development of these lesions.

We wish to acknowledge the cooperation and help of G. D. Searlo & Company, and of Dr. Irwin C. Winters of that company, for supplying drugs and animals for part of this work, and also Parke, Davis & Company, Detroit, Mich., for supplying the benadryl used in this investigation.

EVIDENCE FOR THE ACTIVITY OF A SECOND MEMBER OF THE VITAMIN M GROUP (FERMENTATION FACTOR) IN SPRUE

A CASE REPORT

EDGAR JONES, M.D., HENRY F. WARDEN, M.D., AND
WILLIAM J. DARBY, M.D., PH.D.
NASHVILLE, TENN.

INTRODUCTION

IN THE group of substances¹ loosely referred to as "folic acid" there are at least three related chemical compounds: (1) pteroylglutamic acid² (PGA), which has been synthesized and widely employed clinically and which is identical with the liver *Lactobacillus casei* factor³; (2) pteroyldiglutamylglutamic acid,² an *L. casei* factor which was isolated from "a fermentation residue," and, hence, was termed "fermentation factor,"⁴ and which has not yet been available for widespread clinical testing; and (3) pteroylhexaglutamylglutamic acid⁵ or vitamin B₁₂ conjugate, isolated from yeast⁶ and tested clinically in a limited number of patients.^{7-9, 14} Our initial hypothesis that vitamin M deficiency in the monkey is the experimental analogue of sprue in man^{10, 11} was based in part on the demonstrated activity of pure fermentation factor or pteroyldiglutamylglutamic acid in the vitamin M-deficient monkey and the demonstration of the activity of the related simpler compound, pteroylglutamic acid, in patients with sprue. It has since become evident that this simpler substance (PGA) possesses activity in the monkey.^{12, 13} Suárez and co-workers¹⁴ have reported a patient with sprue who was successfully treated with 4.9 mg. of pteroyltriglutamic acid daily intramuscularly. Castle and associates¹⁵ reported that this material was inactive in patients with pernicious anemia, while Goldsmith¹⁶ has found that it possessed some activity in a patient with nutritional macrocytic anemia. In a preliminary note, Spies¹⁷ stated that a patient with pernicious anemia had exhibited a slight reticulocyte response following the administration of fermentation factor. We have had a sufficient quantity of isolated crystalline fermentation factor* to test its activity in one patient with sprue. Our experience with this case supplies additional evidence for the hemopoietic activity of the factor in this latter condition. Inasmuch as this isolated product is available in but limited quantities and our present supply is exhausted, it appears worth while to report this single case.

From the Departments of Medicine and Biochemistry, Vanderbilt University School of Medicine.

The series of studies dealing with the effects of the vitamin M group, of which this report is a portion, is supported by grants from the National Vitamin Foundation, the Nutrition Foundation, and the International Health Division of The Rockefeller Foundation.

Received for Publication, Feb. 6, 1947.

*We are indebted to Dr. Y. Subbarow and Dr. Stanton M. Hardy of the Lederle Laboratories, Inc., Pearl River, N. Y., for supplying us with this isolated crystalline fermentation factor, lot No. 7-6533.

CASE REPORT

A 52-year-old white woman entered Vanderbilt University Hospital Dec. 19, 1946, with the complaint of recurrent diarrhea of seven months' duration. There had been eight to twelve bowel movements daily for periods of several days to several weeks followed by intervals of four or five days free of diarrhea. The diarrhea was associated with lower abdominal cramping. The stools were described as watery to mushy, of increased bulk, yellow in color, and very foul in odor. Tarry stools had not been noted and gross blood had not been seen. There had been no jaundice, nausea, vomiting, or food intolerance. Moderate anorexia was present. Over the seven-month period there had occurred a weight loss of 80 pounds.

During the four months prior to admission the patient had noted progressive weakness, pallor, exertional dyspnea, and periodic soreness of the tongue. The weakness and dyspnea ultimately confined her to bed for the month preceding admission. There had been swelling of the lower extremities and the eyelids for three months and increasing grayish pigmentation of the hands, arms, and lower legs. No history of excessive blood loss was obtained. The patient's diet had consisted of milk, corn bread, turnip greens, and a few other vegetables; it had included very little lean meat.

Physical examination revealed an extremely ill woman lying flat in bed; she had marked pallor and pronounced generalized wasting of the subcutaneous and muscular tissues. She weighed 120 pounds (54.4 kilograms). The skin was loose, dry, scaly, and of a grayish appearance about the face, neck, arms, hands, and the lower portion of the legs. A few scattered petechiae were present. The hair was dry and without luster. The retinas revealed several small hemorrhagic areas both old and recent. The mucous membranes were pale. The mouth was edentulous. The filiform papillae were atrophic along the margins of the tongue. No abnormality of the lungs was detected. The heart was diffusely enlarged and a loud, low-pitched, blowing systolic murmur was audible over the entire precordium, with the point of maximum intensity in the fourth left interspace. The blood pressure was 98/60 and the pulse rate was 98 beats per minute. There was moderate thickening of the peripheral vessels. The abdomen was protuberant and some tenderness was present in both lower quadrants. The liver and spleen were not palpable and no abdominal masses were detected. Several small hemorrhoids were noted. Moderate pitting edema was present over the sacrum and the upper and lower extremities below the elbows and knees, respectively. The tendon reflexes were hyperactive. The ability to accomplish fine movements of the fingers was impaired and vibratory sense was diminished at the wrists and over the lower extremities. The plantar responses were flexor.

The data for the erythrocyte and leucocyte counts, reticulocytes, hemoglobin, and packed cell volume are given in Fig. 1. A differential count of the white blood cells showed the following percentages: segmented neutrophils, 79; lymphocytes, 14; monocytes, 5; band forms, 1; and eosinophiles, 1. The platelets were scarce and the red blood cells showed marked anisocytosis and poikilocytosis. Aspirated sternal bone marrow revealed 6 per cent megaloblasts and 16 per cent erythroblasts, a picture compatible with a diagnosis of sprue or pernicious anemia. Gastric analysis revealed a histamine refractory achlorhydria. Other laboratory findings included: icteric index, 5; serum albumin, 2.58 Gm. per 100 c.c.; serum globulin, 2.16 Gm. per 100 c.c.; serum calcium, 7.9 mg. per 100 c.c.; and serum phosphorus, 2.4 mg. per 100 c.c. The stool fat content was 62 per cent of the dry weight. Repeated stool examinations revealed no occult blood, ova, or parasites, and no pathogenic organisms were found upon culture. The erythrocyte fragility did not differ from that of the control. The tourniquet test produced a few scattered petechiae. Prothrombin time was 41 per cent of normal. A cephalin flocculation test was negative after twenty-four hours and the thymol turbidity test showed 5 units. Serum levels of vitamins were as follows: vitamin C, 0.1 mg. per 100 c.c.; vitamin A, 39 I.U. per 100 c.c.; carotene, 9 to 16 μ g per 100 c.c.; and tocopherol, 0.45 mg. per 100 cubic centimeters. The vitamin A tolerance test following the oral administration of 200,000 I.U. of vitamin A was as follows: three hours, 43 I.U. per 100 c.c.; five hours, 51 I.U. per 100 c.c.; and nine hours, 46 I.U. per 100 cubic centimeters. A

tocopherol tolerance tests performed simultaneously with the vitamin A tolerance yielded a flat "curve" with values as follows: fasting, 0.45 mg.; three hours, 0.43 mg.; five hours, 0.38 mg.; and nine hours, 0.45 milligram. A glucose tolerance test was invalidated because of the accidental simultaneous subcutaneous administration of 1.5 mg. of histamine.

Fig. 1.—Hematologic response of patient with sprue following the intramuscular administration of fermentation factor. A total dose of 83 mg. was given during a nine-day period. Therapy was then discontinued for four days, following which it was resumed with 5 mg. daily of pteroylglutamic acid orally.

A diagnosis of sprue was made and on the second hospital day the patient was started on 5 mg. of fermentation factor intramuscularly twice daily. On the third day of therapy the reticulocyte count rose to 3.6 per cent, and on the fourth day a peak of 38.2 per cent was reached. The other hematologic data are presented in Fig. 1. On the second day of therapy the patient experienced a sense of well-being and considerable increase in appetite. On the fourth day beginning regeneration of the lingual papillae was noted. During the reticulocytosis the edema was pronounced, to subside within the next six days simultaneously with a decreased weight loss (Fig. 1). On the sixth day of therapy the stools were reduced in number to one or two per day. On the seventh hospital day the patient complained of pain in the left leg associated with tenderness over the femoral triangle. This was associated with

increased edema of this extremity, but there were no changes in skin temperature, color, or sweating. Homan's sign was negative. A lumbar sympathetic novocain block provided no relief. The pain and edema gradually subsided with elevation of the extremities.

A total quantity of 83 mg. of the fermentation factor was administered during the nine days. No additional therapy was instituted until on the thirteenth day of therapy when the patient left the hospital under protest because she wished to return home. She was discharged on 5 mg. of PGA daily by mouth. Continued evidence of hemoregeneration has occurred.

From the beginning of her hospital stay the patient exhibited fever; the temperature ranged from 100 to 100.6° Fahrenheit. Penicillin was administered in doses of 25,000 units every three hours for ten days at the end of which time the temperature became normal.

DISCUSSION

This case met the criteria which we have employed in the diagnosis of sprue.^{10, 11, 12} The patient gave no history of having received previous therapy with liver, and she was maintained during the hospital stay on a diet free of organ meats. The sole hemopoietic agent administered was the pteroyldiglutamylglutamic acid. While spontaneous remissions can occur in sprue, the character and timing of the hematologic changes and the simultaneous clinical improvement indicate convincingly that this remission was due to the administered fermentation factor. It is not valid to attempt to make a quantitative comparison of the response of this patient to the fermentation factor with the expected or standard response of other patients, inasmuch as the course was complicated by thrombophlebitis which may have reduced the height of the maximum reticulocyte response and also the rate of regeneration of red cells. The response exhibited by our patient demonstrates that a patient with sprue who had not been treated previously with liver extract has responded to the fermentation factor, thus supplying the conclusive evidence called for by Suárez and associates¹⁴ of the activity of this substance in sprue without "the participation of exogenous factors of liver extract." This finding, together with the similar clear-cut response of a patient with nutritional macrocytic anemia reported by Goldsmith,¹⁵ indicates that this member of the vitamin M group is hemopoietically active for man as well as for monkeys.

The activity of crystalline fermentation factor in sprue is additional evidence in favor of the hypothesis^{10, 11} that vitamin M deficiency in the monkey is the experimental analogue of sprue in man. Since both sprue and nutritional macrocytic anemia respond to fermentation factor, this is a further link in the evidence for the similarity of these two syndromes.

SUMMARY

A patient with sprue was treated intramuscularly twice daily with 5 mg. of fermentation factor (pteroyldiglutamylglutamic acid). A total quantity of 83 mg. was given over a period of nine days. A maximum reticulocytosis of 38 per cent occurred on the fourth day of therapy. This was accompanied by a rise in erythrocyte count and hemoglobin and clinical improvement.

These results furnish additional evidence of the activity of this member of the vitamin M group in man and of the correctness of the hypothesis that the experimental analogue of sprue is vitamin M deficiency in the monkey.

THIOURACIL AND PROPYLTHIOURACIL: A COMPARATIVE CLINICAL STUDY

WILLIAM H. BEDERWALTES, M.D., AND CYRUS C. STURGIS, M.D.
ANN ARBOR, MICH.

EXPERIMENTALLY, Astwood and Vander Laan¹ found propylthiouracil to be ten times more effective than thiouracil by weight as a goitrogenic agent in rats. Because of this increased effectiveness, propylthiouracil has been used in smaller doses² than thiouracil to produce the same change in thyroid physiology without incurring such a high incidence of toxic reactions to the drug. On the other hand, we have shared with Bartels³ the clinical opinion that propylthiouracil in the doses used at present is not as effective as thiouracil. Before increasing the dosage of propylthiouracil in our thyrotoxic patients, we decided to analyze our results to date statistically to prove or disprove this clinical opinion. In general, the results of this analysis presented herein do not indicate that an increase in propylthiouracil dosage over 150 mg. per day is advantageous in the treatment of thyrotoxicosis.

MATERIAL

Since March, 1946, we have used propylthiouracil as the initial form of treatment in forty-two thyrotoxic patients for a minimum period of six weeks. The distribution of patients treated with this drug, according to the number of months, is demonstrated in Table I.

Pertinent data necessary to compare the response rate of the two groups treated are presented in Table II. Other factors not listed in this table were identical in these two groups, since we directed the treatment in each group in the same manner but, starting in March, 1946, merely changed from thiouracil to propylthiouracil in the initial treatment of thyrotoxic patients. The general plan of treatment has been outlined in previous publications.⁴⁻⁷

Examination of Table II reveals major discrepancies at three points in these comparative data. In our opinion, the difference in the number of patients treated will not invalidate a comparison because (1) a statistical analysis of the first forty-seven patients treated with thiouracil⁴ was not significantly different from the final analysis of the entire group of ninety-eight patients presented here and (2) we have continued the comparative graphs to be presented later in this paper only to the end of the first six weeks of treatment so that a maximum number of points would determine the position of the right end of the propylthiouracil line. The 25 per cent difference in the number of patients hospitalized

Received for publication, Feb. 7, 1947.

TABLE I. DISTRIBUTION OF PATIENTS TREATED WITH PROPYLTHIOURACIL BY NUMBER OF MONTHS

MONTHS	PATIENTS
1 to 2	12
2 to 4	15
4 to 6	12
6 to 8	3

TABLE II. FACTORS AFFECTING COMPARISON OF THIOURACIL- AND PROPYLTHIOURACIL-TREATED GROUPS

	THIOURACIL	PROPYLTHIOURACIL
Number of patients	98	42
Per cent hospitalized initially	76	50
Average period of hospitalization	5.5 wk.	5.4 wk.
Average initial B.M.R. per cent	38	41
Average frequency of B.M.R.s		
Inpatients	1 per wk.	1 per wk.
Outpatients	1 per 1.5 mo.	1 per 1 mo.
Per cent of nodular goiters	39	40
Average dose	0.6 Gm.	0.150 Gm.

initially in each group is insignificant in view of the graph comparing the results in each hospitalized group. The marked difference in drug dosage then is the only significant variable between the two groups.

RESULTS

The following graphs (Figs. 1 to 3) summarize the results of statistical comparison of the group of ninety-eight patients treated with 0.6 Gm. of thiouracil per day and the forty-two patients treated with 0.15 Gm. of propylthiouracil per day.

Illustrated in Fig. 1 is the fact that the rate of descent of the basal metabolic rate in both groups of hospitalized patients is almost identical. In general, the clinical change in the patient corresponded to the change in the basal metabolism.

It is demonstrated in Fig. 2 that in patients treated with propylthiouracil the initial response of the thyrotoxic state to treatment accompanied by bed rest is greater than when the patient is ambulatory, although the eventual result is apparently the same. Since all outpatients in our series were urged to spend a minimum of twelve hours a day in bed, there might be even greater discrepancies if the outpatients' activities were not restricted. It should be noted also that in general we have hospitalized the more severely toxic patients as an initial precaution.

An equal rate of improvement in the thiouracil- and propylthiouracil-treated groups is shown in Fig. 3. This similarity of response, in spite of a clinical opinion to the contrary, is reminiscent of our early use of thiouracil.⁴ Although we did not feel that 0.4 Gm. per day of thiouracil was the optimum dose, a statistical comparison of the patients treated on 0.4 and 0.6 Gm. per day later revealed no significant difference in therapeutic effect. It should be noted that the basal metabolic rate in thyrotoxic patients in Michigan does not fall at the rate of 1 per cent per day, as noted by Bartels⁵ for patients on the Atlantic Coast, but at a rate of less than 1 per cent every two days.

Fig. 1.

Fig. 2.

DISCUSSION

This statistical comparison of the two drugs indicates that 150 mg. of propylthiouracil per day is an adequate dose for most thyrotoxic patients. The only toxic reactions we have observed in nine months of use of this new anti-thyroid agent are (1) drowsiness during the first two weeks of administration in about 30 per cent of the patients and (2) acneform dermatitis of the face in one patient, which disappeared when the dosage of the drug was reduced by 50 mg. per day. The lack of toxic reactions with this agent in our series is in keeping with the observation of Astwood and Vander Laan.² However, Bartels³ mentioned three cases of agranulocytosis presumably due to propylthiouracil. Since propylthiouracil lacks toxicity mainly by virtue of its decreased dosage, the occurrence of the more severe forms of toxic reactions such as agranulocytosis and drug fever might be logically expected if the amount of drug administered is increased. Fortunately, our experience indicates that an increase in dosage is not necessary to achieve results comparable to those with thiouracil.

Fig. 3.

SUMMARY

1. A statistical comparison of ninety-eight thyrotoxic patients treated with 0.6 Gm. of thiouracil per day and forty-two treated with 0.15 Gm. of propylthiouracil per day reveals practically identical effectiveness of the two drugs in these doses.

2. An initial period of bed rest coupled with the administration of propylthiouracil is accompanied by a greater favorable initial response than in the ambulatory-treated patient, although the end result appears to be the same.

3. In Michigan the average rate of response of the basal metabolic rate of thyrotoxic patients treated with either drug is less than a 1 per cent fall every two days, in contrast to a fall twice as great reported from the Atlantic Coast.

4. The incidence of toxic reactions with propylthiouracil is much less than with thiouracil.

5. Severe toxic reactions well might be encountered if the present dosage of propylthiouracil is significantly increased.

6. The available data indicate that 150 mg. is probably the most satisfactory maximum dosage of propylthiouracil.

We are indebted to the staff of the Department of Internal Medicine and to Dr. F. A. Coller and Dr. R. W. Buxton of the Department of Surgery for their cooperation in making the patients available to us for study.

OBSERVATIONS ON THE DIURNAL EXCRETION OF UROBILINOGEN IN THE URINE OF NORMAL SUBJECTS AND OF PATIENTS WITH LAËNNEC'S CIRRHOSIS

EDMUND PELLEGRINO, ARTHUR J. PATEK, JR., ANNE COLCHER, AND
BEATRICE DOMANSKI
NEW YORK, N. Y.

THERE have been many reports on the diurnal variation of urobilin or urobilinogen excretion in normal and pathologic states. These studies have been performed with techniques differing in sensitivity and reliability and in the main on small groups of cases. In 1893 Grimm¹ and in 1897 Sallet² independently showed (1) that the excretion of urobilin during the day exhibits two peaks, one in midmorning and the other in midafternoon and (2) that nocturnal excretion of this substance constitutes a very small portion of the twenty-four hour excretion. Subsequent reports³⁻¹⁰ are in general agreement that the maximal urobilin or urobilinogen excretion takes place in the afternoon and that minimal excretion takes place at night. Variations have been attributed to digestive and metabolic activity.

Wallace and Diamond,¹⁰ for example, tested the urobilinogen excretion in morning and afternoon urines of 125 medical students. Their method depends upon the red color reaction produced by Ehrlich's aldehyde reagent with urobilinogen. A rough estimate of urobilinogen concentration is made by diluting the urine until the pink color disappears, a dilution of 1:20 being considered the outer limit of normal. Fifty specimens obtained in the afternoon showed a slightly higher concentration of urobilinogen than seventy-five specimens obtained in the morning. White and associates,⁸ employing the Wallace and Diamond method, tested for urobilinogen at two-hour intervals during the day in fifteen normal subjects. "The variation in the results was found to be moderate and all within normal limits. . . . The afternoon specimens showed more urobilinogen than the morning specimens in about one-half of the cases." Steigmann and Dyniewicz⁹ determined the hourly excretion of three normal subjects over a twenty-four hour period. In one subject the maximal excretion was at 4 P.M. and in one at 8 P.M., whereas the third subject showed peaks at 10 A.M. and 4 P.M. In comparing the morning and afternoon urine samples of twelve patients with urobilinogenuria from various diseases, Watson and co-workers¹¹ found the concentration of the afternoon specimens to be higher in nine of twelve instances.

Most of the preceding reports are concerned with the relative concentrations of urobilinogen excreted in morning and afternoon urine samples. It seemed desirable to measure the quantity excreted per unit time as well, since a highly concentrated urine might give a false impression of the total excretion. With

From the Research Service, First (Columbia) Division, Goldwater Memorial Hospital, Department of Hospitals, and the Department of Medicine, Columbia University.
Received for publication, Jan. 22, 1947.

the introduction by Watson and co-workers¹¹ of a simplified method for the quantitative determination of urobilinogen, it became feasible to re-examine the problem of diurnal excretion of urobilinogen in a series of patients with liver disease. It was of practical interest to ascertain (1) whether there is an optimal period for urobilinogen excretion and (2) whether the daily pattern of excretion is constant in the same patient and in different patients. With this purpose the urobilinogen excretion was determined at three periods of the day in a series of normal subjects and in patients with cirrhosis of the liver.

METHOD

The method employed is essentially that described by Watson and associates¹¹ in which the Ehrlich color reaction is measured in a photoelectric colorimeter. In our procedure a few minor changes were introduced. Instead of a blank composed of reagents added in reverse order, as employed by these authors, we have employed a blank of 22 per cent HCl, which is the concentration of HCl contained in the Ehrlich reagent itself. The procedure is as follows: unknown, 2.5 c.c. urine, 2.5 c.c. "Ehrlich Reagent,"* 5 c.c. saturated sodium acetate; blank, 2.5 c.c. urine, 2.5 c.c. 22 per cent HCl,† 5 c.c. saturated sodium acetate.

It seemed essential to standardize the procedure with reference to time and temperature, since these factors influence the intensity of color reaction. The first two reagents are mixed and placed in a water bath at 37° C. for ten minutes. Colorimetry then is performed directly after the addition of the sodium acetate solution. The color obtained in this manner is generally maximal for the reaction.

Readings were made with the Klett photoelectric colorimeter with a No. 56 filter‡ and calibrated against the Pontacyl violet stock solution described by Watson and associates.¹¹

Results are expressed in terms of Ehrlich units per hour (as proposed by Watson), since the reaction is not specific for urobilinogen but measures other Ehrlich-reacting substances as well. These chromogens are said to parallel roughly the excretion of urobilinogen.

The subjects of this study were thirty-six hospitalized patients with cirrhosis of the liver observed during a period of two years on the Research Service (First Division) of the Goldwater Memorial Hospital. The diagnosis was established in each case by history, physical findings, and laboratory tests of liver function. All but four cases had the diagnosis confirmed either by biopsy of the liver or by necropsy. Twenty cases were classified as in severe failure and sixteen in moderate failure. All patients were being treated according to a dietary regimen previously described.¹² This consisted of a nutritious diet, rich in protein and supplemented with 50 Gm. of brewers' yeast daily. No fluid or dietary restrictions were imposed preceding or during the test.

The patients voided at 7 A.M. Urine excreted from 7 to 10 A.M., 10 A.M. to 1 P.M., and 1 to 4 P.M. was then collected in separate bottles. Determinations were performed on each three-hour specimen within fifteen minutes of its collection. In this manner 180 series of determinations or a total of 540 single determinations were performed on thirty-six patients. The distribution of tests in this group was as follows: thirteen patients had one serial determination; five had three or four determinations; ten had five or more; and eight had ten or more.

The control series consisted of thirty-nine healthy subjects who were medical students and hospital personnel ranging in age from 20 to 35 years. Fifty-seven tri-daily determinations or a total of 171 single determinations were made. The distribution of tests in this group was as follows: twenty-seven subjects had one serial determination; seven had two determinations; four had three; and one subject had four.

*0.7 Gm. *p*-dimethylaminobenzaldehyde, 150 c.c. concentrated HCl, 100 c.c. distilled H₂O.

†150 c.c. concentrated HCl, 100 c.c. distilled H₂O.

‡There is little difference between values obtained with a No. 54 filter and those with a No. 56 filter. The procedure also has been carried out with a Junior Coleman colorimeter at 565 millimicrons.

RESULTS

The periods of maximal urine urobilinogen excretion both in normal subjects and in patients with liver cirrhosis are shown in Table I. There were fifty-seven serial determinations in normal subjects, of which sixteen were highest in the morning, nineteen at midday, nineteen in the afternoon, and three showed no peak of excretion. In patients with cirrhosis (180 serial tests), sixty-four showed maximal excretion in the morning, fifty-two at midday, and sixty-four in the afternoon.

Fig. 1.

Fig. 2.

Fig. 1.—Diurnal urine urobilinogen excretion in 39 normal subjects. Mean values are similar for the three periods of the day. Few determinations exceed 0.5 unit per hour.

Fig. 2.—Diurnal urine urobilinogen excretion in 36 patients with liver cirrhosis. The pattern is similar to that of the normal subjects. Because of a wider distribution of values the scale has been reduced in this illustration.

The data are presented graphically in Figs. 1 and 2. Each histogram shows the number of determinations falling within a given range of urobilinogen excretion in units per hour. The distribution of these values does not differ significantly during the three periods, either for the normal subjects or the patient group. The similarity in the form of the graphs for the three periods suggests that no peculiar trend of urobilinogen excretion takes place during the day.

TABLE I. PERIODS OF MAXIMAL UROBILINOGEN EXCRETION

TIME	NORMAL SUBJECTS		PATIENTS WITH LIVER CIRRHOSIS	
	NUMBER OF INSTANCES	PER CENT	NUMBER OF INSTANCES	PER CENT
7 to 10 A.M.	16	29.6	64	35.5
10 A.M. to 1 P.M.	19	35.2	52	29.0
1 to 4 P.M.	19	35.2	64	35.5

The mean value of the normal subjects was 0.3 unit per hour. In 95 per cent of the tests made on normal subjects, values of 0.5 unit or less per hour were obtained. This finding is in agreement with the normal range obtained by Watson and co-workers.¹¹ In the case of liver cirrhosis the mean urinary excretion was 0.6 unit per hour. There was a much wider spread of values in this patient group, that is, from 0.03 to 5.4 units per hour. *Although all patients with cirrhosis of the liver showed increased urobilinogen excretion at one or another time, there were many tests that fell within the normal range.* In fact, fifty-five per cent of 540 tests on these patients fell within the normal range. The need for repeated tests becomes obvious.

The diurnal urobilinogen excretion of eight patients who had ten or more serial determinations made is shown in Table II. In each case the diagnosis of liver cirrhosis was confirmed by biopsy. Two points are illustrated in Table II: first, that while some patients favor one period for maximal excretion others do not; second, that the pattern of urobilinogen excretion may vary in the same patient at different times.

In general, there was a poor correlation between the severity of liver disease and the degree of urobilinogen excretion (Table II). The poor correlation stands out in contrast to the experience of others with acute hepatitis in which there appears to be close agreement between urobilinogen excretion and the activity of the disease process. However, when jaundice was present in patients with cirrhosis consistently higher values were obtained. This has been observed previously by Steigmann and Dyniewicz.¹²

Morning and afternoon peaks of excretion were noted in only a few instances. The peaks described by Grimm,¹ Saillet,² and Bang⁵ were transitory and took place two or three hours after meals. Since the present study involves consecutive three-hour periods, those sharp variations might have been neutralized by the long periods of collection.

Salen,⁴ Bang,⁵ and White and associates⁸ found no relation between the volume of urine and the amount of urobilinogen excreted. Our data tend to confirm their findings. However, it appears that urobilinogen excretion can be increased by excessive intake of water. This effect was tested in two normal subjects. After ingestion of 1,500 c.c. of water one subject showed little, if any, increase in urobilinogen excretion on two tests. In another subject the urobilinogen excretion after the ingestion of 1,500 and 5,000 c.c., respectively, was two and three times greater than that of the preceding control periods.

SUMMARY AND CONCLUSIONS

1. Urine urobilinogen excretion was determined for three successive periods of three hours each in thirty-nine normal subjects and in thirty-six patients with cirrhosis of the liver.

2. The mean urine urobilinogen excretion per hour was 0.3 Ehrlich unit for the normal subjects and 0.6 for the patients.

3. The period of maximal urobilinogen excretion varied in the different subjects and also in the same subject at different times.

4. There was a poor correlation between the degree of urobilinogenuria and the clinical severity of the liver disease.

A COMPARISON OF THE NUTRITIVE VALUE OF THE PROTEINS IN MIXED DIETS FOR DOGS, RATS, AND HUMAN BEINGS

D. M. HEGSTED, VIRGINIA KENT, A. G. TSONGAS, AND F. J. STARE
BOSTON, MASS.

THE evaluation of the nutritive value of proteins has usually been done with rats, although some data have been collected using other species such as the canine, man, and the avian. In general, it is known that the supplementation of vegetable diets with a high quality protein such as meat causes an improvement in the nutritive value of the ration for all species which have been studied. The essential amino acids for the rat, human being, dog, and chick are similar but not the same. It seems likely that the quantitative relationships of the essential amino acids may also vary among the species. Such differences, should they occur, could only mean that various proteins would have different biologic values for different species. The relatively poor nutritive value of casein for the chick due to its low arginine and glycine content is a specific example, but whether such differences occur among the other common species of laboratory animals is unknown.

Biologic value, usually defined as the per cent of absorbed nitrogen retained in the body, depends upon the amino acid composition of the absorbed protein. There may also be species differences in the digestibility of proteins. Although the reasons for differences in the digestibility of proteins are obscure, specific amino acid linkages, proteinase inhibitors, amount of fiber in the food, method of preparation of the food or protein, and amount and kind of the various proteinases in the digestive apparatus are factors which may be involved. There is little reason to believe that all factors would be of equal importance in different species. A predominantly carnivorous animal with a short digestive tract might be expected to digest the proteins in vegetable matter less effectively than predominantly vegetarian species.

With these theoretic possibilities in mind, several diets which had previously been studied with human subjects¹ were fed to rats and dogs. In this paper the figures obtained for the digestibility and biologic values in these species are compared to those previously reported for man.

EXPERIMENTAL

The diets which were examined as protein sources have been previously described.¹ The all-vegetable diet called Diet IB contained no animal protein. Approximately 50 per cent of the protein in this diet came from white bread made without milk solids; other percentages were: 7.6 from corn meal, 4.4 from rice, 13.3 from potatoes, 16.3 from other vegetables (including lettuce, carrots, onions, and tomatoes), and 8.4 from fruits (including orange juice, apple sauce, and peaches).

¹From the Department of Nutrition, Harvard School of Public Health, and the Department of Biological Chemistry, Harvard Medical School.

Supported in part by a grant-in-aid from the American Meat Institute, Chicago, Ill.
Received for publication, Feb. 2, 1947.

When supplements were added, each constituent of Diet IB was decreased by one-third and the amount of protein thus removed was replaced by an equivalent amount of protein from the supplement. In this paper the diets are identified according to the supplement used, that is, meat, soy flour, wheat germ, or bread.

During the studies on human subjects¹ additional meals were prepared and dried at 40° C. in front of fans. After drying, the mixed diets were ground, analyzed for protein by the Kjeldahl method and for fat by ether extraction, and stored in the refrigerator until used in the present studies.

Studies With Dogs: Ten dogs were used in these studies. They varied in weight from 8 to 15 kilograms and were free from parasites. At the beginning of each study they were fed a diet essentially free of nitrogen of the following percentage composition: sucrose, 83; cottonseed oil, 9; salt mixture,² 4; and cod-liver oil, 2. Crystalline vitamins* were added to supply 200 γ thiamine chloride, 400 γ riboflavin, 200 γ pyridoxine, 1.5 mg. pantothenic acid, 2.5 mg. nicotinic acid, and 100 mg. choline per 100 Gm. of diet. The diet was fed in amounts to supply approximately 80 calories per kilogram of body weight. When the protein supplements were fed, the amount of the nitrogen-free diet was decreased proportionately to keep the calorie intake approximately constant.

In general, the plan followed was to feed the nitrogen-free diet for a period of ten to twenty days. The urine and feces were collected during the last week. The urine was combined to give composite samples representing a three- and a four-day period. The feces were homogenized in a Waring blender with water and combined in a similar manner. Charcoal markers were used to delimit the feces into appropriate periods. Following the nitrogen-free period, supplements of the experimental diets were given. Generally supplements of the all-vegetable Diet IB were fed for one week followed by a week during which the diet containing meat was used to supply a similar amount of nitrogen. During the next week another level of Diet IB was fed and following this the meat diet at a similar level, etc. However, in some animals only Diet IB was fed, the levels being increased each week. The amount of supplement which was given varied from 0.50 to 1.80 Gm. of nitrogen per dog per day.

Considerable difficulty was met in completing satisfactory studies. The diets were apparently not palatable for dogs, at least after a depletion period, and many of the dogs went off feed within a few days after the supplement was given and had to be discontinued. Thus, more data were collected on the all-vegetable Diet IB than on the diet containing meat, and studies on wheat germ and soy flour supplemented diets were not attempted with dogs. Studies similar to those reported by Allison and Anderson³ were unsuccessful for similar reasons, since the higher levels of the diets were even more difficult to feed.

Studies With Rats: These studies were made with adult male rats. They were fed a nitrogen-free diet of the following percentage composition: sucrose, 84; corn oil, 10; salts, 4; cod-liver oil, 2; and vitamins at the same levels

*Supplied by Merck & Company, Inc., Rahway, N. J.

used in the diets for dogs. When supplements were added, these replaced sucrose and sufficient corn oil to maintain the fat content at 10 per cent. All supplemented diets contained 7.5 per cent protein ($N \times 6.25$).

The experimental procedure was to feed the animals a nitrogen-free diet for twenty days, collections being made during the last eleven days in three periods of four, three, and four days each, respectively. Following this the diet containing protein from the all-vegetable diet was fed for twelve days, collections being made the last eleven days in four, three, and four day periods, respectively, as before. Then a similar twelve-day period followed during which one of the other diets was tested. The food intake during the nitrogen-free period was recorded and a like amount fed during the other periods. By this procedure each supplemented diet was compared to the all-vegetable diet. Twelve rats were used for each experiment.

Biologic values and digestibilities were calculated in the conventional manner. Digestibility is the per cent of fed protein absorbed and biologic value the per cent of absorbed nitrogen retained.

Studies also were made using young growing male rats (average weight 45 grams). In one experiment groups of six rats each were fed ad libitum on diets containing 7.5 per cent protein of a similar composition to those used for adult rats. In a second experiment using the same number of animals, each six animals of comparable weight receiving the different diets were restricted in food intake to the amount eaten by the animal having the lowest intake. This was usually the animal receiving the unsupplemented diet, but in some instances the bread-supplemented diet produced the least gain and food intake. In this study all the diets contained 9.6 per cent protein.

RESULTS

The results obtained with dogs are shown in Table I. The average results indicate an increase in digestibility and of biologic value of approximately 10 per cent by the inclusion of meat in the diet. The standard deviations are large for each value, especially of those for biologic value. It is our impression that there is a great variation in the ability of dogs to "handle" diets such as those which are high in vegetable matter.

TABLE I. DIGESTIBILITY AND BIOLOGIC VALUE OF DIETS FOR ADULT DOGS

SUPPLEMENT TO DIET IB	DIGESTIBILITY		BIOLOGIC VALUE	
	NUMBER OF TESTS	AVERAGE \pm STANDARD DEVIATION	NUMBER OF TESTS	AVERAGE \pm STANDARD DEVIATION
None	27	80.0 \pm 7.7	16	67 \pm 21
Meat	11	90.3 \pm 7.1	11	77 \pm 14

The data from the adult rats are shown in Table II. These data were treated somewhat differently than those from the dogs, since for each rat data were available on the all-vegetable diet for comparison with the supplemented diet. The values obtained for Diet IB in each experiment involving twelve rats are recorded, and the significance of the difference between this value and the observed value for the supplemented diet is given. It may be noticed

TABLE II. DIGESTIBILITY AND BIOLOGIC VALUE FOR ADULT RATS OF SUPPLEMENTED DIETS COMPARED TO ALL-VEGETABLE DIET

SUPPLEMENT	DIGESTIBILITY				BIOLOGIC VALUE				NET VALUE		
	DIET IB	SUPPLEMENT	DIF-FERENCE	PROBABILITY OF SIGNIFICANCE	DIET IB	SUPPLEMENT	DIF-FERENCE	PROBABILITY OF SIGNIFICANCE	DIET IB	SUPPLEMENT	DIF-FERENCE
Meat	75.9	79.7	+ 3.8	0.15	68.1	80.7	+12.6	0.01	51.6	64.0	+12.4
Soy flour	79.1	91.4	+12.3	0.01	72.7	77.0	+ 4.3	0.10	57.4	70.2	+12.8
Wheat germ	83.3	89.2	+ 5.9	0.05	73.2	77.7	+ 4.5	0.03	61.0	69.1	+ 9.1
Average	79.4				71.3						

that whereas all three supplements allowed some improvement in both biologic value and digestibility, the increase in digestibility due to the addition of meat and the increase in biologic value from soy flour supplementation were not significant at the 5 per cent level.

The results with young growing rats are presented in Table III. In these studies all three supplements clearly improved the nutritive value of the diet, whether the diets were fed ad libitum or restricted to the intake of the poorest animal. In neither experiment are meat, wheat germ, or soy flour supplements significantly different. In these studies the diet containing additional bread studied with human beings¹ was also fed. A diet containing skim milk powder as the sole source of protein was included for comparison in this experiment. Skim milk powder appeared only slightly better than the meat-supplemented diet, while bread did not improve or decrease the nutritive value of the diet. The efficiency of protein utilization is not presented since, as has been shown,⁴ this is a function of the weight of the animals.

TABLE III. WEIGHT GAIN IN YOUNG RATS RECEIVING VARIOUS DIETS

SUPPLEMENT TO DIET IB	AD LIBITUM FEEDING† (GM.)	RESTRICTED INTAKE† (GM.)
None	16.6 ± 7.0	8.0
Meat	61.0 ± 9.0	21.5
Wheat germ	57.0 ± 13.0	24.5
Soy flour	54.2 ± 16.3	22.5
Bread	17.5 ± 7.0	11.0
Skim milk powder*	73.0 ± 16.5	

*Skim milk powder as the sole source of protein, not as a supplement to Diet IB.

†During fifty days on diets containing 7.5 per cent protein.

‡During twenty-one days on diets containing 9.6 per cent protein.

In additional experiments groups of animals receiving the basal all-vegetable and the meat-supplemented diets were placed in activity cages. No significant differences in spontaneous activity were observed either with restricted or ad libitum feeding.

DISCUSSION

In the previous publication¹ the digestibility and biologic value of the protein in the various diets for human beings were estimated, although the excretions on a nitrogen-free diet were not actually determined. The fecal nitrogen on a nitrogen-free diet was estimated by feeding the all-vegetable diet at

three different levels and extending the regression line to zero protein intake. The urinary excretion on a nitrogen-free diet was estimated to be 2 mg. of nitrogen per basal calorie. The reliability and criticisms of these methods have been discussed,⁵ but it is believed that they are useful for comparative purposes.

The present results have been summarized with those obtained on human subjects in Table IV. In general, it may be said that the results on rats and dogs are similar to those obtained with human beings although there are some apparent differences. Our most reliable data on all species were obtained with the all-vegetable diet, and it appears that digestibility of this diet was relatively better in man than in the other two species. The biologic values, on the other hand, are in the same range for all species, although somewhat lower for dogs. This may be some evidence for the correctness of the assumed figure for the endogenous nitrogen excretion used in the calculations on the data for man. The net protein values suggest that man utilized the all-vegetable diet somewhat better than the other two species, because of more efficient digestion. This result, however, may be due to the methods used in determining the metabolic fecal nitrogen. Bosshardt and Barnes⁶ have shown that fecal nitrogen of mice receiving a nitrogen-free diet underestimates the metabolic fecal nitrogen occurring when proteins are fed. These authors believe that the method used in these studies on human beings is preferable to feeding nitrogen-free diets. If this is true, the digestibility of the proteins in rats and dogs has been underestimated. These studies appear to confirm the observations of Bosshardt and Barnes.

TABLE IV. COMPARISON OF NUTRITIVE VALUE OF PROTEINS OF VARIOUS DIETS IN MAN, RATS, AND DOGS

SUPPLEMENT	ADULT MAN			ADULT RATS			ADULT DOGS			YOUNG RATS	
	DIGESTIBILITY	BIOLOGIC VALUE	NET	DIGESTIBILITY	BIOLOGIC VALUE	NET	DIGESTIBILITY	BIOLOGIC VALUE	NET	GAIN IN THREE WEEKS	
										AD LIBITUM (GM.)	LIMITED INTAKE (GM.)
None	87.5	72.5	63.5	79.4	71.3	56.5	80.0	66.7	53.0	16.6	8.0
Meat	89.0	80.4	71.5	79.7	80.7	64.0	90.3	76.7	69.0	61.0	21.5
Soy flour	83.8	70.6	59.2	91.4	77.0	70.2				57.0	22.5
Wheat germ	85.8	88.8	76.2	89.2	77.7	69.0				54.2	24.5
Bread	90.8	70.0	63.5							17.5	11.0

Man and the rat appeared to react in nearly identical fashion to the addition of meat to the diet. Digestibility was not improved, but the figures for biologic value were increased by approximately 10 per cent. The dogs, however, apparently digest the meat-supplemented diet better in addition to showing an increase in biologic value of 10 per cent. The overall net gain for the dogs was thus considerably more than in the other two species, 16 per cent compared to 8 per cent.

The data on man and the rats do not agree on the soy flour-supplemented diet. Whereas no improvement was noted by this addition for human beings in either biologic value or digestibility, both of these showed improvement in

the rats. Wheat germ supplements, while resulting in a gain in the net protein value of like amounts in the two species, showed the improvement in man entirely in biologic value whereas it was greatest in digestibility for the rat. As has been pointed out,¹ the data on soy flour and wheat germ in man are much less extensive than on the basal or meat-supplemented diet. Thus, we are unable to state that the apparent species differences in these two proteins are real.

The results on young growing rats are similar to those obtained with adult rats and, except for soy flour, also for those obtained with man. Supplements of meat, soy flour, or wheat germ apparently were of essentially equal effectiveness as they were in the adult animals. As in man, bread additions neither improved nor decreased the nutritive value. It is of interest that whereas meat supplementation caused an improvement of 8 per cent in the net protein value for adult animals, the relative improvement was much greater in the growing animals.

Recently Mitchell and Block⁷ have presented convincing evidence that the biologic value of proteins as determined with rats bears a close relationship to their amino acid composition and may be estimated from the amino acid content. If, as suggested by the present data, the rat and man react similarly to various proteins, the value of the available data on proteins determined with rats is considerably enhanced. It further suggests that the percentage composition of the ideal protein for the two species is similar and lends support to the method of calculating amino acid requirements previously proposed by Stare, Hegsted, and McKibbin⁸ and extended by Harte and Travers.⁹ Since growing rats apparently classify proteins in a similar manner to adult rats, the results of such simple feeding experiments may be applicable for the evaluation of human dietaries as well.

CONCLUSION

Human subjects, rats, and dogs have been used to determine the biologic value of proteins in natural diets. The rat appeared to react in an exactly comparable manner to the human being when meat was added to the diet. Digestibility was not improved but the biologic value was increased 10 per cent. With the dog, on the other hand, both digestibility and biologic value were improved by meat supplementation.

The rat in these studies appeared more comparable to the human being than the dog.

Young growing rats, either by paired or ad libitum feeding, appear to classify these proteins in a similar manner to adult rats.

PROTHROMBIN TIME STUDIES ON HUMAN BEINGS AND EXPERIMENTAL ANIMALS

G. A. NITSHÉ, JR., H. W. GERARDE, AND H. F. DEUTSCH
MADISON, WIS.

THE one-stage assay of prothrombin has been shown to be affected by the concentration of fibrinogen.¹ By diluting a given plasma with a fibrinogen solution, sharper end points are realized at the higher dilutions, and the assay range may be extended to considerably higher plasma dilutions than is possible when the dilution of the substrate is not corrected. Preliminary *in vitro* prothrombin time studies had suggested that plasma fibrinogen concentrations might introduce changes in the apparent prothrombin levels as measured on saline diluted samples. The work reported here entails a study of the prothrombin time variable in experimental animals and in human beings as reflected by the clotting times of saline and fibrinogen dilutions of plasma in relation to the actual plasma fibrinogen level.

EXPERIMENTAL

All prothrombin determinations were carried out according to the method outlined by Deutsch and Gerarde.¹ The bovine fibrinogen was prepared according to the method of Seegers and associates.² It was used in the form of a 0.3 per cent solution (clottable fibrinogen) at pH 7.2 to 7.4. The major portion of the thromboplastin used in this work was prepared from rabbit brain according to the method of Quick.³ One preparation however, was made according to the method of Link and associates.⁴ After extraction of the thromboplastin with saline according to Quick's³ method, an equal volume of a pH 7.4 buffer that was 0.05 M in cacodylate and diethyl barbiturate and 0.025 M in CaCl_2 was added. This mixture was centrifuged lightly and 1.0 c.c. portions of the supernatant were added to 0.5 c.c. of various saline or fibrinogen dilutions of a given plasma. The length of time for clotting at 25 degrees (± 1 degree) was determined visually. All plasmas were obtained by mixing 9 c.c. of blood with 1 c.c. of 0.1 M sodium oxalate, the resultant oxalated plasma being considered 100 per cent according to the usual convention. Fibrinogen assays were carried out by the method as outlined by Reiaer,⁵ the fibrin nitrogen being estimated by micro-Kjeldahl or colorimetrically following nesslerization.

Rats used for observations on the effect of caffeine, sodium salicylate, and vitamin K on prothrombin time were maintained two weeks or longer prior to the experiment on the relatively low vitamin K diet as used by Link and co-workers.⁶ The rabbits used were fed exclusively on a commercial rabbit-pellet diet. All drugs with the exception of vitamin K were administered by stomach tube; the latter compound was given by intraperitoneal injection.

RESULTS

Caffeine Effects.—In the higher saline dilutions of plasma (10 per cent plasma) the small amount of fibrinogen present makes difficult the determination of the appearance of the relatively small fibrin clot formed. A plasma to which

Received for publication, Jan. 31, 1947.

various levels of fibrinogen have been added prior to saline dilution forms clots at 10 per cent plasma concentrations that are more readily discerned although no additional prothrombin has been added to the system.¹ It also has been indicated previously that the ingestion of caffeine by rabbits may alter the prothrombin time of saline dilutions of such plasma by virtue of its raising the fibrinogen level. In further testing this hypothesis rabbits were fed caffeine citrate at the level of 100 mg. per kilogram, and the prothrombin times of saline and fibrinogen dilutions of the plasma as well as the plasma fibrinogen levels were determined before and after such medication. Little variation in the prothrombin times of saline- and fibrinogen-diluted plasma was seen at the higher plasma concentrations (80 to 10 per cent). Therefore, prothrombin times were determined only for a 10 per cent dilution of plasma in 0.15 M NaCl and for 10 and 1 per cent dilutions in 0.3 per cent fibrinogen. Saline dilutions of plasma in excess of 1:10 (10 per cent plasma) were not carried out due to the difficulty and often impossibility of determining the end point of the clotting reaction. The results of these determinations on eight rabbits are shown in Table I. In addition, eight male rats weighing from 250 to 300 grams, which had been maintained on the relatively low vitamin K diet of Link and co-workers⁶ for at least two weeks, were given 100 mg. of caffeine citrate per kilogram. The findings for these rats are shown in the caffeine data of (Table II). The marked increases in plasma fibrinogen values of these rats were found forty-eight hours after the ingestion of caffeine citrate. It can be seen from the data that the plasma fibrinogen levels vary considerably after treatment; in general, a distinct rise was noted which is in agreement with the work of Field and associates.⁷ Although the 10 per cent dilutions of rabbit plasma in saline tend toward slightly shorter prothrombin times due to the enhanced fibrinogen levels, the effect is by no means clear-cut. Rat plasma showed slightly lengthened values in all dilutions as compared with the controls (Table II). The marked increases in plasma fibrinogen values of these rats were not reflected in shortened prothrombin times of the 10 per cent plasma in saline as would be expected from the differences of the saline and fibrinogen

*The vitamin K used was Synkayvite (tetrasodium 2-methyl-1, 4-naphthohydroquinone diphosphoric ester).

†From a control group which showed no fibrinogen by the assay method used.

diluted systems of the 10 per cent rat plasma concentrations. The prothrombin times of the 1 per cent plasma in 0.3 per cent fibrinogen while indicating a mild hypoprothrombinemia do not fall in line with the results on rabbits (Table I), where even in the presence of a mild hypoprothrombinemia there were in general slightly shortened prothrombin times in the 10 per cent plasma concentration in saline of rabbits showing enhanced fibrinogen values.

As will be discussed later, there are various factors which may be tending to give results which are difficult to evaluate in the "one-stage" prothrombin assay. The interpretation by Field and associates⁸ that shortening of prothrombin times as shown by some rabbits is due to an enhanced level of prothrombin is not borne out by the clotting times of 1 per cent plasma in fibrinogen. The lengthened prothrombin times of both rat and rabbit plasma at this dilution are indicative of a decreased amount of prothrombin as a result of caffeine ingestion. The results of the clotting times of 10 per cent rabbit plasma in saline are quite analogous to the results of Quick⁹ who could demonstrate no hyperprothrombinemia as the result of caffeine feeding. Interesting is the report of Scherf and Schlachman¹⁰ who found a rapid lowering of the prothrombin time of the plasma of patients who had received aminophyllin and theophyllin.

Salicylate and Vitamin K Effects.—It appeared that the hypoprothrombinemia experienced in rats as a result of salicylate ingestion⁶ might likewise be a reflection of the assay technique as influenced by a lowered plasma fibrinogen level. Experiments studying the effect of sodium salicylate and vitamin K were carried out under conditions similar to those employed by Link and co-workers,⁶ except for the inclusion of fibrinogen dilution prothrombin assay procedures.

These experiments were conducted on male rats weighing 250 to 300 grams and maintained under the same conditions as those on the caffeine experiment. The animals were given 100 mg. sodium salicylate by stomach tube and prothrombin studies were carried out approximately twenty hours later. The effect of such a level of sodium salicylate accompanied by an intraperitoneal injection of 5 mg. equivalents of vitamin K (Synkavite: tetrasodium 2-methyl-1, 4-naphthohydroquinone diphosphoric ester), as well as the effect of vitamin K alone, was determined on individual groups of animals. The analytic findings resulting from this medication as compared with control rats receiving no treatment are shown in Table II.

It is apparent from the data that sodium salicylate induces a hypoprothrombinemia and that the effect observed by Link and associates⁶ is not one of a decrease of fibrinogen level as suggested by Deutsch and Gerarde.¹

Vitamin K counteracts the effect of the sodium salicylate; this effect does not appear to be due to the enhanced plasma fibrinogen level elicited by vitamin K administration. The data of Table II, however, in no way suggest that vitamin K can induce hyperprothrombinemia as has been stated by Field and Link¹¹ and Richards and Shapiro.¹² Mikhlin¹³ has indicated that vitamins K₁ and K₂ as well as related synthetic products are without effect on the blood of normal animals and man. However, both Mikhlin^{13, 14} and Babuk¹⁵ report that a vitamin K concentrate prepared from maize stigmas accelerated the normal coagulability of the blood in the dog, rabbit, rat, and man. They attributed this effect to a hyperprothrombinemia, although in view of our findings it is possible that this noted effect may be due to other factors.

Afibrinogenemic Rats.—Interestingly in the control rats studied there appeared two afibrinogenemic animals. While 10 per cent saline dilution and even undiluted plasma failed to clot in the usual prothrombin assay, dilution of the plasma of these animals with fibrinogen gave prothrombin times which indicated normal or enhanced values of plasma prothrombin. It would appear that the diet used by Link⁶ tends to produce low plasma fibrinogen levels. Similar responding animals have been found on this diet by Link.¹⁶ These two animals showed no tendency toward hemorrhage as has been reported for afibrinogenemic human beings by various authors.¹⁷⁻²⁰ In fact, the animals studied here in whose plasma no fibrinogen could be demonstrated were able to survive heart puncture.

Thromboplastin.—In part, the discrepancy between the results of Field and associates⁸ and of Quick⁹ might be due to differences in the activities of the thromboplastin preparations used. We have found the prothrombin time of rabbit plasma at 25 degrees with the Quick³ thromboplastin preparation to be shorter than that recorded by Link^{4, 8} for rabbit plasma at 37 degrees. Although Quick⁹ has likewise commented on the lowered activity of the Link⁴ thromboplastin, we are not aware of a specific demonstration of such a difference. To test this experimentally, pooled macerated rabbit brains were divided into two equal portions and thromboplastin was prepared by both the method of Link⁴ and that of Quick.³ The prothrombin times of fibrinogen and saline

dilutions of rabbit and human plasma were determined using these thromboplastin preparations under identical conditions. The results for human plasma which were similar to those found for rabbit plasma are shown in Fig. 1 and clearly indicate the greater activity of the Quick² thromboplastin preparation. In this respect Scherf and Schlachman¹⁰ used Russell viper venom as the thromboplastin which in comparison with the Quick thromboplastin is relatively low in activity. From this it appears that low activity thromboplastins may possibly show up plasma fibrinogen increases as apparent prothrombin increases. Prothrombin measurements of such plasma should be carried out at high plasma dilution in the presence of a constant substrate (fibrinogen) level if the results of the one-stage prothrombin time assay method are to be interpreted in terms of prothrombin content.

Fig. 1.—Comparison of clotting times of saline and fibrinogen dilutions of a single human plasma using Link⁴ and Quick² thromboplastin.

Prothrombin Variations in Human Beings.—The relatively wide variations in prothrombin levels for essentially normal rats and rabbits as reflected by the clotting time of their 1 per cent solution of plasma in fibrinogen are interesting. It has been claimed by Quick²¹ that the prothrombin levels of normal human beings fall within a narrow range. Other authors, however, indicate that considerable variations exists.^{22, 23} Warner and associates²⁴ indicate that the effects of plasma antithrombin are minimized by high dilution of the plasma. Prothrombin assays at a plasma concentration of 1 per cent in the presence of a constant level of fibrinogen are probably more indicative of prothrombin content than assays

conducted in relatively concentrated plasma or in saline dilutions where the enzyme substrate tends to become the limiting factor. Application of the fibrinogen dilution technique was applied to the plasmas of a series of normal human subjects. Considerable differences in the prothrombin levels as reflected by variations in the prothrombin time were found by assay of 1 per cent plasmas. The variations encountered in the saline-diluted 10 per cent plasma were relatively smaller. These data are shown in Table III. There appears to be little correlation between plasma fibrinogen levels and the variations in the prothrombin times of plasma diluted to a level of 10 per cent with saline or fibrinogen. In general, however, the fibrinogen-diluted plasmas showed a slightly shortened prothrombin time.

To determine whether markedly enhanced plasma fibrinogen levels would affect the prothrombin time, a series of clinical cases tending in this direction were studied. They represented varied pathologic conditions with plasma fibrinogen values extending from normal to extremely high levels as shown in Table IV. The prothrombin times of 1 per cent plasma in fibrinogen were analogous to those found in normal individuals. However, the individual variations encountered were much greater. This was true also for the 10 per cent plasma clotting times. A noticeable difference in many cases was the lengthening of the prothrombin times of the 10 per cent plasmas diluted with fibrinogen as contrasted to the saline dilution. This was particularly evident in the samples of plasma having the higher fibrinogen levels. In the normal series,

as previously noted in all except one instance, the prothrombin times of 10 per cent plasma diluted with fibrinogen were shorter than the corresponding saline dilutions.

In previous *in vitro* studies fibrinogen was added to plasma to provide a system containing variable amounts of fibrinogen with a constant level of prothrombin.¹ Dilution of such a plasma with saline shows that the fibrinogen addition definitely affects the apparent prothrombin level as indicated by shorter prothrombin times in the higher dilutions. In our present work similar high fibrinogen level plasmas as occurring in various pathologic conditions were studied. The results (Table IV) are difficult to appraise. It would appear that fibrinogen fluctuations might be accompanied by variation in such clotting entities as inhibitors and prothrombin. A possible factor tending to introduce variations is the rate at which prothrombin is converted to thrombin. Thus, the discrepancies of prothrombin content of various animal plasmas as determined by the one-stage method of Quick²¹ and the two-stage method of Warner and associates²⁵ appear to be conversion rate differences rather than absolute prothrombin levels. It is possible that even within a given species this conversion rate may vary. In addition, the presence of inhibitors for prothrombin, thrombin, and thromboplastin likewise affect clotting reactions. The true evaluation of the blood clotting mechanism as revealed by "one-stage" prothrombin assays should take into account all of these factors as well as the factors we have studied. Since simultaneous control of all recognized clotting factors in the "one-stage" type of assay would be extremely difficult, it would appear that assay techniques built around the "two-stage" assay would be more feasible for the true evaluation of prothrombin. Here individual reactions can be somewhat segregated, controlled, and studied independently. The "one-stage" clotting picture represents the summation of various reactions, and it is difficult to appraise the effect of any one given reaction.

SUMMARY

Various experimental and clinical conditions involving variation in fibrinogen and prothrombin levels have been studied.

The apparent hyperprothrombinemia experienced by some workers as a result of caffeine feeding appeared as a mild hypoprothrombinemia when prothrombin time assays were carried out at a 1 per cent plasma concentration in the presence of 0.3 per cent fibrinogen. The effect of sodium salicylate on rats is to induce a definite hypoprothrombinemia with little alteration in fibrinogen level. Vitamin K while counteracting the action of sodium salicylate *does not* in itself produce hyperprothrombinemia. A series of normal human subjects and clinical patients showed relatively wide variations in prothrombin levels as revealed by prothrombin times of 1 per cent dilutions of plasma. The marked fluctuation in plasma fibrinogen content did not correlate with expected prothrombin times of saline dilutions; this indicates a need for the evaluation of clotting factors in addition to those studied here.

THE CORPUSCULAR CONSTANTS OF COLLEGE WOMEN OF THE NORTH CENTRAL STATES*

GLADYS KINSMAN LEWIS,† MARGARET A. OHLSON,‡ DENA CIDERQUIST,§
AND EVA G. DONILSON||

HEMATOLOGIC data on 4,550 normal college women, 16 to 30 years old, inclusive, were reported recently by Ohlson and associates.¹ Included in these were data from 1,348 individuals, 17 to 24 years old, inclusive, on whom the hemoglobin concentration, the number of red cells, and the packed cell volume were determined on the same samples of blood. From these values, which include data from the nutrition laboratories of Iowa State College, Kansas State College, University of Minnesota, and Oklahoma Agricultural and Mechanical College, the corpuscular constants of Wintrobe² have been calculated. Complete information on the experimental methods used in the study were given in the previously mentioned report.¹

The corpuscular constants (mean corpuscular hemoglobin, mean corpuscular volume, and mean corpuscular hemoglobin concentration) were first introduced and defined by Wintrobe² in 1929. In 1934 he³ summarized the data available at that time and reported values for the corpuscular constants on approximately 700 individuals, 274 of whom were normal women between the ages of 18 and 30 years, inclusive, from different parts of the United States and Denmark. The mean values for the women of this age range were: mean corpuscular hemoglobin, 28.8 micromicrograms; mean corpuscular volume, 87.0 cubic microns; and mean corpuscular hemoglobin concentration, 33.1 per cent. Since 1934 the corpuscular constants have been determined for subjects of both sexes in different parts of the world.⁴⁻¹⁴ In 1942, while referring to values for corpuscular constants found since 1934, Wintrobe¹⁵ stated, "Reports made since that time, with one exception, are either in exact agreement with those given or differ so slightly that the mean values remain the same when these additional data are used."

The present study of the corpuscular constants of 1,348 college women offers the largest series of values reported to date.

RESULTS AND DISCUSSION

In Table I are given the number of subjects and the mean values for mean corpuscular hemoglobin, mean corpuscular volume, and mean corpuscular hemoglobin concentration for each group of women studied and for the subjects as a

Oklahoma	243	29.2	2.4	0.15	88.3	5.2	0.33	33.1	2.3	0.15
All four states	1348	29.3			90.3			32.5		
Wintrobe's report on women from the United States and Denmark	274	28.8			87.0			33.1		

whole. The standard deviations and the standard errors of the means are also included for each state group of subjects. For ease of comparison the values for corpuscular constants of the women between the ages 18 and 30 years, inclusive, given in Wintrobe's 1934 report have been included in the table.

The mean values of the corpuscular constants are somewhat different for the four groups of women studied. The respective maximum and minimum mean values are: mean corpuscular hemoglobin, 30.7 and 28.8 micromicrograms in Minnesota and Iowa, respectively; mean corpuscular volume, 92.7 and 88.3 cubic microns in Minnesota and Oklahoma, respectively; and mean corpuscular hemoglobin concentration, 33.2 and 31.7 per cent in Minnesota and Kansas, respectively. It is interesting to observe that the Minnesota group, in which the bloods were taken uniformly under basal conditions, show the highest values for all three corpuscular constants, although the mean values for hemoglobin, number of red cells, and packed red cell volume were the lowest of any state group.¹ Only in one of the four states, Iowa, is the mean corpuscular hemoglobin as low as 28.8 micromicrograms, the mean value reported for women of a similar age range by Wintrobe. In no instance is the mean corpuscular volume as low as Wintrobe's 87.0 cubic microns. In two states, Minnesota and Oklahoma, the values for mean corpuscular hemoglobin concentration are practically the same as the 33.1 per cent reported by Wintrobe, while in the other two states lower values are found.

A study of the significance of the differences between the mean values for the four groups shows that significant differences occur for all three corpuscular constants (Table II). For mean corpuscular hemoglobin, three out of six possible comparisons show highly significant differences between means, that is, critical ratios of 3.0 or more. Highly significant differences are found in five out of six instances for mean corpuscular volume and in four out of six for mean corpuscular hemoglobin concentration.

Even though there are significant differences between the means for each constant, there seems to be ample justification for putting the data of the four state groups together to obtain mean values of the constants for the 1,348 subjects as a whole. The reasons that prompt such a conclusion are (1) the marked inter- and intraindividual variations observed in the different states during the

$$*C.R. = \frac{m_1 - m_2}{S_{x \text{ diff.}}}, \text{ where } S_{x \text{ diff.}} = \sqrt{\frac{S_1^2}{N_1} + \frac{S_2^2}{N_2}}; m_1 \text{ and } m_2, S_1 \text{ and } S_2, \text{ and } N_1 \text{ and } N_2$$

denote the means, the standard deviations of the means, and the number of cases, respectively; and $S_{x \text{ diff.}}$ stands for the standard error of the difference between the means.

present study and (2) the wide variation in the data used by Wintrobe to establish his means for these constants. The range of mean values used by Wintrobe was: 28 to 31 micromicrograms for mean corpuscular hemoglobin, 82 to 93 cubic microns for mean corpuscular volume, and 32 to 34 per cent for mean corpuscular hemoglobin concentration.

By reference to Table I, it is seen that the corpuscular constants for the subjects of the present study as a whole may be compared readily with the comparable values reported by Wintrobe for women of a similar age range. The respective values are: mean corpuscular hemoglobin, 29.3 and 28.8 micromicrograms; mean corpuscular volume, 90.3 and 87.0 cubic microns; and mean corpuscular hemoglobin concentration, 32.5 and 33.1 per cent. The similarity of these values in each case is quite striking, particularly so for mean corpuscular hemoglobin and mean corpuscular hemoglobin concentration. When one considers that Wintrobe's range for mean corpuscular volume, 82 to 93 cubic microns, was much wider than for the other constants, the difference of 3.0 cubic microns would seem to have little, if any, greater significance than the differences found for the other constants.

This study and a previous one,¹ as well as numerous other reports in the literature, serve to emphasize the fact that the mean values for hemoglobin, red cell count, and packed red cell volume, and the mean corpuscular constants derived therefrom, show considerable variation between the different groups studied in this country and abroad. The lack of uniformity in these values, even when the numbers of subjects in the studies are large, leads to speculation as to the reasons for these differences. To what extent they are due to the experimental procedure employed and what role environmental conditions (temperature, humidity, altitude), race, and dietary factors play in their origin are points that are not clearly understood and require further elucidation.

SUMMARY

1. Values for mean corpuscular hemoglobin, mean corpuscular volume, and mean corpuscular hemoglobin concentration are reported on 1,348 women from

colleges or universities in four states, Iowa, Kansas, Minnesota, and Oklahoma.

2. The mean values found for these corpuscular constants are somewhat different for the four state groups. The respective maximum and minimum values are: mean corpuscular hemoglobin, 30.7 and 28.8 micromicrograms; mean corpuscular volume, 92.7 and 88.3 cubic microns; and mean corpuscular hemoglobin concentration, 33.2 and 31.7 per cent.

3. When the results on the 1,348 subjects are considered as a whole, the mean values for the corpuscular constants are 29.3 micromicrograms for mean corpuscular hemoglobin, 90.3 cubic microns for mean corpuscular volume, and 32.5 per cent for mean corpuscular hemoglobin concentration.

TWO POPULAR FALLACIES REGARDING Rh

PRELIMINARY REPORT OF SOME THOUGHT-PROVOKING OBSERVATIONS

FIRST LIEUTENANT PAUL G. HATTERSLEY, MEDICAL CORPS, ARMY OF THE
UNITED STATES

WITH the tremendous mass of literature on the Rh factor which has accumulated in the seven years since its discovery, it is inevitable that certain fallacious ideas should have reached print and should persist in the minds of many of their readers. One or two of these fallacies have been repeated in one paper after another without an adequate investigation of their origin or of their accuracy.

It is the purpose of this paper to present a preliminary report of some observations made in this laboratory which would seem to indicate the fallaciousness of two commonly held beliefs regarding Rh.

Fallacy 1: Only a Small Percentage of Rh-Negative Persons Can Become Sensitized by Transfusion With Rh-Positive Blood.—Wiener¹⁻³ has stated variously that between one in fifty and one in twenty-five Rh-negative persons who are "exposed to the Rh antigen" become sensitized, and his statements have been repeated widely elsewhere. He further states⁴ that the incidence of sensitization by Rh-positive pregnancy, and by transfusion, is about the same. Unger⁵ goes so far as to say that "The fact is now recognized that when repeated transfusions of Rh-positive blood are given to an Rh-negative patient, antibody response to the Rh antigen develops in approximately one in twenty-five patients." Yet, neither Wiener nor Unger refers to experimental or clinical data as a basis for his statements.

Actually there is much recent evidence from several sources that sensitization may occur in many more than one in twenty-five Rh-negative individuals who receive Rh-positive blood. Diamond and co-workers,⁶ in a series of 2,500 servicemen who had been transfused under wartime conditions without regard for Rh type, were able to demonstrate anti-Rh antibodies in the serum of about 50 per cent of the Rh-negative individuals. Ross,⁷ in a smaller series, likewise found Rh antibodies in nearly 50 per cent of the Rh-negative bloods.

In a similar survey now under way in this laboratory, we have examined bloods of a group of servicemen who have at some time in the past received transfusions, presumably without the benefit of Rh typing. These bloods were classified as Rh-positive or Rh-negative, according to their reactions with standard Rh₀ typing serum. All the Rh negatives and the majority of the Rh positives were subtyped with sera of Rh' and Rh'' specificity. All sera were examined then for Rh antibodies according to the method of Diamond and Denton,⁸ a single drop of serum being incubated in a small tube with a drop of

The opinions expressed in this paper are those of the author and do not reflect necessarily the official attitude of the United States Army.

Received for publication, Jan. 27, 1947.

2 per cent suspension of Rh₁Rh₂ cells in 30 per cent bovine albumen. Parallel tests were set up using Rh-negative cells. Sera agglutinating the Rh-positive cells were then titrated, using the same cell suspension both in saline and in albumen. The serum dilutions for the latter were made in normal serum, as suggested by Levine and Bernstein.⁹ For comparison, all sera showing anti-Rh activity were also tested with the blocking technique of Wiener.

The results closely approximate those of Diamond and of Ross. Of the first 122 bloods examined, twenty were negative for the Rh₀ factor; of these, two were type Rh' and one was Rh". Of these twenty sera, eleven (or 55 per cent) contained Rh antibodies, all of the blocking or incomplete variety, and all were inactive against saline-suspended cells. Titers against Rh₁Rh₂ cells in albumen ranged from 1:1 to 1:5120, while blocking titers ranged from 0 to 1:32. The findings are summarized in Table I.

TABLE I. TITERS WITH RH₁RH₂ CELLS

SERUM	SALINE	ALBUMEN	BLOCKING
1	—	1:4	1:1
2	—	1:64	1:2
3	—	1:2	1:1
4	—	1:8	1:4
5	—	1:32	1:2
6	—	1:128	1:16
7	—	1:8	1:4
8	—	1:4	1:1
9	—	1:5120	1:32
10	—	1:64	1:4
11	—	1:1	—

It is evident that if these sera had been examined with saline-suspended cells only, all would have been discarded as containing no antibodies. Yet, many of these patients had had one or more transfusion reactions, a few quite severe. There can be little question that they were sensitized to the Rh factor by transfusion.

In evaluating these findings it should be kept in mind that in choosing the subjects for this survey, all patients were included who gave any history of receiving whole blood overseas, or at small hospitals in this country, regardless of the number of transfusions or the elapsed time since the last one. Most of them had not received blood for many months. It seems quite likely that if they had been examined sooner after their last transfusions, the percentage showing antibodies would have been even higher.

Further evidence of this sort comes from the work of Diamond⁸ and of Wiener and Sonn-Gordon¹⁰ in sensitizing Rh-negative volunteers by repeated injections of Rh-positive blood. Although there was a great deal of variation in the ease with which the volunteers were sensitized, the percentage who eventually developed antibodies when sensitizing doses were continued was extremely high.

It would appear then that we must discard the notion that only one in twenty-five Rh-negative persons who are transfused with Rh-positive blood may become sensitized. Rather, it must be assumed that every Rh-negative patient is capable of developing Rh antibodies and should be transfused only with Rh-

negative blood. Transfusion reactions due to Rh sensitization are probably much more common than often is realized. Most of them can and should be avoided.

Fallacy 2: Blocking Antibodies Are Always of Rh₀ Specificity.—In 1944 and 1945 Race,¹⁰ Wiener,¹¹ and Diamond¹² independently reported the discovery of an antibody which, while it did not of itself agglutinate Rh-positive cells, specifically combined with them so as to prevent their agglutination by a known Rh agglutinating serum. This blocking antibody was described as specific for the Rh₀ (D) element of the cells, blocked Rh₁ cells behaving like Rh' cells, and blocked Rh₂ cells like Rh''. This specificity has repeatedly been emphasized in the literature. Wiener⁴ has even suggested that this phenomenon be used in identifying antisera of unknown specificity, blocked Rh₁ and Rh₂ cells being used in place of Rh' and Rh'' which are often not available.

Several new techniques since have been developed to demonstrate these blocking antibodies by their active agglutination of Rh-positive cells in various viscous media, and these more sensitive methods have largely replaced the blocking test in routine use. Yet, there have been very few reports of further study of Rh antisera with these new techniques to determine whether blocking antibodies of other than pure Rh₀ specificity ever occur. Diamond and Abelson,¹³ in describing their slide test for the blocking antibody, remarked that "Sera classified as anti Rh₀ are capable (by this technique) of agglutinating Rh' cells." Callender, and associates¹⁴ also have described a serum with a blocking antibody of anti-c (Hr') specificity. In neither case, however, did the authors pursue the matter further.

It is then of interest to report the findings in an analysis of the anti-Rh sera encountered in our survey of transfused patients. Sera found to agglutinate Rh₁Rh₂ cells in albumen were tested for specificity by the same technique, using Rh₀, Rh', and Rh'' cell suspensions in albumen. The findings on the first ten sera are summarized in Table II.

TABLE II. SERA OF TRANSFUSED MEN; TITERS WITH VARIOUS TYPES OF CELLS IN SALINE AND 30 PER CENT BOVINE ALBUMEN

SERUM	CELL TYPE					
	Rh ₀		Rh'		Rh''	
	SALINE	ALBUMEN	SALINE	ALBUMEN	SALINE	ALBUMEN
1	—	1:4	—	1:1	—	—
2	—	1:64	—	—	—	—
3	—	1:2	—	—	—	—
4	—	1:8	—	1:1	—	—
5	—	1:32	—	1:1	—	—
6	—	1:64	—	1:4	—	1:1
7	—	1:8	—	—	—	—
8	—	1:4	—	—	—	—
9	—	1:5120	—	1:1280	—	—
10	—	1:32	—	1:1	—	1:1

It may be seen that, in spite of their complete lack of activity in saline, six of the ten sera had unmistakable activity against Rh' cells in albumen, and two against Rh''. These reactions were checked with the rabbit antihuman globulin technique of Coombs and associates,¹⁵ with excellent agreement.

Furthermore, it was possible to demonstrate that Serum 9, with the highest titer of anti-Rh' antibodies, was capable of blocking Rh' cells in saline so that subsequently they could not be agglutinated by a standard anti-Rh' serum.

In order to determine whether these findings would be limited to patients sensitized by transfusions, ten unselected sera from Rh-negative women who had been sensitized by Rh-positive pregnancies were evaluated similarly. The findings are summarized in Table III.

TABLE III. SERA OF SENSITIZED RH-NEGATIVE WOMEN; REACTIONS WITH VARIOUS TYPES OF CELLS IN SALINE AND 30 PER CENT BOVINE ALBUMEN

SERUM	CELL TYPES					
	Rh ₀		Rh'		Rh''	
	SALINE	ALBUMEN	SALINE	ALBUMEN	SALINE	ALBUMEN
11	—	++	—	—	—	—
12	—	++++	—	++++	—	—
13	—	++++	—	—	—	—
14	++++	++++	—	++++	—	—
15	++++	++++	+	++++	—	—
16	—	++++	—	++++	—	—
17	+	++++	—	++++	—	—
18	—	++++	—	++++	—	++++
19	++++	++++	—	++	—	—
20	++++	++++	+	++++	—	—

It may be seen that whereas the usual Rh'-typing serum consists of a mixture of Rh' agglutinins and Rh₀-blocking antibodies, quite the opposite situation is illustrated by Serum 14, a standard Rh₀ agglutinating serum which proved to contain Rh'-blocking antibodies as well. Considering the twenty sera examined, of the eighteen which had no activity against Rh' cells in saline, eleven (or 60 per cent) agglutinated these same cells in albumen, while two others with weak Rh' agglutinins clumped these cells very much more strongly in albumen. While none of the twenty showed Rh'' agglutinins in saline, three (or 15 per cent) agglutinated Rh'' cells in albumen.

It is realized that this series is small, but these preliminary observations appear sufficient to cast considerable doubt on the oft repeated statement that blocking antibodies are always of Rh₀ specificity.

SUMMARY

Two popular opinions regarding the Rh factors are discussed with evidence which suggests that they are fallacious:

1. *Only a small percentage of Rh-negative persons can become sensitized by transfusion with Rh-positive blood.* Evidence is presented that more than 50 per cent of such persons may develop antibodies. It is concluded that Rh-negative individuals should be transfused only with Rh-negative blood.

2. *Blocking antibodies are always of Rh₀ specificity.* Twenty antisera from Rh-negative persons sensitized by transfusion or by pregnancy were examined for activity against Rh' and Rh'' cells in albumen and in saline. Although none caused agglutination in saline, Rh' antibodies active in albumen were demonstrated in 60 per cent and Rh'' antibodies in 15 per cent.

PROGRESS

METABOLIC COMPLEXITIES OF PELLAGRA

PHILIP HANDLER, PH.D.
DURHAM, N. C.

THE current concepts of metabolism in pellagra commenced with the identification¹ of niacin as the blacktongue preventive principle of liver whose existence had been established by Goldberger and Wheeler² and the occurrence of this compound as part of codehydrogenases I and II.^{3, 4} The numerous investigations reported since these papers have added many pieces of information, but the over-all picture is one which has grown steadily more perplexing. Although the fundamental significance of the pyridine nucleotides in cellular respiratory mechanisms is beyond dispute, attempts to correlate the behavior of such systems with the usual manifestations of niacin deficiency have met with no success.^{5, 6} However, it does seem likely that failure of these systems is involved in the development of anemia in niacin-deficient dogs.⁷

The nature of the precipitating factor which results in blacktongue crises, characterized morphologically by lesions in the mucosa of the gastrointestinal tract and chemically by acidosis and dehydration, is as yet unknown. This crisis usually occurs within forty to sixty days after an adult dog is placed on a diet containing corn meal and the animal dies within a few days. Yet, the entire symptom complex disappears after a week of vigorous parenteral saline therapy, frequently never to return, although the animal survives for another three to six months.⁸ While the niacin and coenzyme concentrations of the tissues of dogs in blacktongue are not reduced materially below normal, those of dogs successfully treated with salt solution, which survive several months longer, are dramatically reduced and death at this point does seem to be related to coenzyme deficiency. This situation scarcely seems compatible with simple niacin deficiency as the sole etiologic factor in the pathogenesis of blacktongue. It has been noted that the niacin content of the diets on which pellagra and blacktongue develop are not really remarkably low in niacin but contain an amount equal to that which must be added to prevent disease. Considering the rapid development of these diseases, this is a most unusual behavior for a simple vitamin deficiency. When it was found that the buccal manifestations of blacktongue did not appear for many months in dogs on a synthetic ration very low in niacin content, that when they did appear they were not accompanied by acidosis or dehydration, and that one-third of the dogs simply declined steadily and died after three to seven months in much the same manner as dogs on corn meal rations who have been successfully treated with salt solution, it was suggested by the present author⁸

From the Department of Biochemistry, Duke University School of Medicine.
Received for publication, Jan. 27, 1947.

that corn is of positive etiologic significance in the development of blacktongue (and, presumably, of pellagra) and not merely a food of relatively low niacin content. While this was a revival of a time-honored, but hitherto unproved, thesis, it was based on experimental evidence. The same suggestion had been made earlier by Aykroyd and Swaminathan⁹ after an appraisal of the niacin intake of pellagrous and nonpellagrous populations.

A new approach to this problem was offered by the finding that a suitable admixture of corn grits and a synthetic ration resulted in a suppression of rat growth which could be overcome by niacin¹⁰ or by tryptophane.¹¹ At this writing, data are available concerning the effects of tryptophane on apparent niacin deficiency only in the rat and chick. This is particularly unfortunate since these findings in the rat make it difficult to understand the development of fatal niacin deficiency in the adult dog on purified rations, providing what would seem to be an otherwise adequate tryptophane intake (22 per cent casein)⁵ and the use of almost identical rations as the basis for a niacin assay with pups.¹² Since tryptophane administration results in an increased urinary excretion of niacin derivatives, particularly N¹-methylnicotinamide, in rats,¹³ the possibility exists that tryptophane may serve as a precursor for niacin synthesis.

The presence of considerable quantities of a substance which has not been identified positively but with properties suggestive of quinolinic acid (pyridine, 2,3-dicarboxylic acid) in rat urine after tryptophane administration²⁰ offers a clue to the possible pathway of such a biologic synthesis of nicotinic acid from tryptophane. The observation that pyridoxine-deficient rats do not excrete extra N¹-methylnicotinamide when given tryptophane¹⁴ but do excrete abnormal quantities of xanthurenic acid,¹⁵ a derivative of tryptophane, also makes a metabolic relationship between niacin and tryptophane seem likely. This defect in the metabolism of tryptophane in pyridoxine-deficient rats may be related to the demonstrated functioning of pyridoxine derivatives in decarboxylase¹⁶ and transaminase systems.¹⁷ This niacin-tryptophane-pyridoxine relationship seems all the more significant when one notes that there exists reason to suspect that the fluorescent compound, F₁, whose excretion increases with the development of pellagra¹⁸ may be the pyridoxic acid found in the urine of normal individuals after the administration of pyridoxine.¹⁹

It is somewhat disconcerting to note that increasing the casein intake of rats does not increase the N¹-methylnicotinamide excretion in their urine.¹⁴ However, this situation yet may provide an explanation for the situation just described, in which fatal niacin deficiency was produced in adult dogs on a diet containing 22 per cent casein and no corn meal. This recalls the failure of Goldberger and Tanner to treat successfully persons with pellagra with as much as 90 Gm. of casein per day.²¹

Since the "yield" of niacin derivatives in rat urine after tryptophane administration is quite low on a percentage basis, the possible conversion of tryptophane to niacin can be established best by a tracer experiment involving the administration of tryptophane labeled with isotopic carbon or nitrogen. The work of Krehl and associates²² offers an alternative, albeit not mutually exclusive, mechanism for the tryptophane-niacin relationship. They observed

that niacin administration increased the efficiency of tryptophane utilization on a corn grits-low casein diet from 30 to 70 per cent. Similar studies with pyridoxine would probably yield a qualitatively similar result. Indeed, such a relationship might be demonstrable between each member of the B complex and the essential amino acids, although the present instance may operate via a specific metabolic path.

Of potentially great significance in this connection and elsewhere is the observation²³ that, like corn meal, the addition of gelatin or a tryptophane-free hydrolysate of fibrin to a low casein (9 per cent) ration markedly depressed the growth of rats and this could be prevented by the further addition of niacin or tryptophane. One explanation which suggests itself is that by improving the supply of other essential amino acids the relative deficiency in tryptophane is more marked and that such a situation is more deleterious to the animal's well-being than the original state of affairs. However, this would not account for the action of niacin. It may be that the increased over-all protein metabolism increases the demand for niacin much as an increased carbohydrate metabolism increases the demand for thiamine. There are, of course, other analogies to this situation, but it certainly suggests that an evaluation of the factors leading to the development of pellagra must consider not only the tryptophane content of the diet but the total amount of protein as well. That corn protein is tryptophane deficient has long been recognized and has been considered as a possible etiologic factor in pellagra by many investigators including Wilson, Mitchell, and Goldberger. However, no suggestion of a specific protein-tryptophane-vitamin P-P relationship was made in the literature until the recent work of the Wisconsin laboratory.^{10, 11} Further investigation of the metabolic interrelationships of pyridoxine, tryptophane, niacin, and dietary protein is essential to the establishment of a rational concept of the etiology and pathogenesis of pellagra.

Complex as these interrelationships now seem, to the situation must be added the existence of toxic principles in corn and possibly other cereals. While the older literature contains many such speculations, no such material had been isolated until 1933 when Stockman and Johnston²⁴ reported that they had obtained from corn feed meal (corn from which the starch and oil had been removed) an acid which gave an insoluble lead salt and an easily crystallizable and soluble sodium salt. No attempt to establish the identity of this substance was made. Single doses of about 1 Gm. given to Rhesus monkeys resulted in drowsiness and mild paresis. Repeated doses produced drowsiness, general paresis, paralysis, coma, and death. On histologic examination the only significant lesions were found in the nervous system. They consisted largely of degenerative changes not unlike those reported from time to time as occurring in persons with pellagra, and more recently in dogs.²⁵ Guinea pigs responded in the same fashion but rabbits seemed resistant to the substance unless very large doses were employed, in which event they died after a few hours. It is unfortunate that no studies were made with dogs. A similar material was obtained from oats and from one batch of rye but not another. Considering the symptomatology reported, it is interesting to speculate upon the possible relationship of this material to the toxic principles responsible for favism, lathyrism, and "non-

convulsive ergotism" (which seems to be related to the ingestion of large quantities of rye bread uncontaminated with ergot) and the therapeutic and prophylactic use of niacin in these states.

Woolley²⁶ has presented a preliminary report in which is described the isolation from corn meal of an organic base, perhaps a pyridine derivative, which inhibited the growth of mice when added in small concentration to a synthetic ration. Such a substance may behave as a niacin (or, perhaps specifically, niacinamide) antagonist in the manner already described for beta-acetopyridine.²⁷

A most recent pertinent report in this regard is that of Kodicek and associates²⁸ who observed that the inclusion of 1.5 mg. per cent of indole-3-acetic acid (the plant hormone, heteroauxin) in a 10.5 per cent casein diet suppressed rat growth, and this could be prevented by niacin or tryptophane fed at 1 and 20 mg. per cent, respectively. Since the corn meal content of indoleacetic acid has been estimated variously as between 20 and 100 mg. per kilogram,^{29, 30} it seems possible that this may be the long sought, toxic principle of corn. Further, since both the auxins and the corn toxin of Stockman and Johnston was obtained by initial heavy metal precipitation, it may be that these authors obtained a crude preparation of indoleacetic acid thirteen years ago, although they failed to identify it as such. Woolley's pellagrenic agent is an organic base which can be extracted from an alkaline medium with chloroform and so cannot be indoleacetic acid, although the possibility remains that it is a basic precursor or bound form of heteroauxin.

The excretion of indole derivatives in pellagrous urine has long been known. These have included indican^{32, 33} and indolethylamine.³⁴ While indoleacetic acid itself has not been isolated, it is known that the red pigment observed in the urine of persons with pellagra and blacktongue dogs, thought to be a porphyrin by Beekh and co-workers,³⁵ is a mixture of urorosein and a substance similar to indirubin.^{36, 37} While nothing is known of the indirubin-like pigment, save for its indole nucleus, urorosein is actually excreted as uroroseinogen which was shown by Herter³⁸ to be identical with indoleacetic acid which is converted to the red pigment urorosein on standing in strongly acid solutions in the presence of traces of nitrite or other oxidizing agents.

Until recently we had considered the presence of these indole compounds the result of unusually active bacterial putrefaction in the bowel due to the serious disturbances of gastrointestinal function occasioned by pellagra. The demonstration of a tryptophane-nicotinic acid relationship^{10, 11, 13, 14, 22, 23} then seemed to indicate a revision of this concept, although the presence of excessive quantities of indole derivatives in the urine of subjects on a purportedly tryptophane-deficient diet appeared irrational. The presence of such large quantities of heteroauxin in corn meal renders such reasoning unnecessary. However, it should be realized that the urine of normal rats on a synthetic diet gives a positive urorosein reaction roughly proportional to the level of dietary casein and greatly intensified by feeding extra casein or tryptophane.³³ If this reaction is due solely to indoleacetic acid (no other known derivative of trypto-

phane gives this reaction), this substance which cannot be further metabolized²⁸ appears to be a normal product of mammalian tryptophane metabolism.

Much work remains to be done to establish the mode of action of indoleacetic acid in order to determine its role in the etiology of pellagra. On purely structural grounds one might conceive readily of it as an inhibitor of the metabolism of either nicotinic acid or tryptophane or both. Does it block the conversion of tryptophane to niacin, inhibit coenzyme synthesis from niacin or niacinamide, or the conversion of niacin to niacinamide or vice versa, or perhaps stimulate the metabolism of mammalian cells as it does certain plant cells and thereby increase the niacin requirement as previously postulated for the effect of administration of tryptophane-deficient proteins? This might be clarified by studies with synthetic plant hormones (such as, 2,4 dichlorophenoxyacetic acid) which contain no indole nucleus. Dubos²⁷ has reported that indoleacetic acid and a number of related substances inhibit the growth of *Mycobacterium tuberculosis*, *Streptococcus hemolyticus*, *Streptococcus salivarius*, and *Shigella paradysenteriae*, and this inhibition of growth can be reversed by tryptophane in a concentration about ten times that of the inhibiting auxin. If this phenomenon represents a structural inhibition similar to those of the vitamin analogues studied by Woolley, it is most unusual to find the inhibitor functioning at a lower concentration than the normal metabolite and suggests a more specific role for the auxins. It is unfortunate that no study was made of nicotinic acid in this connection. On the other hand, in similar studies in this laboratory²⁹ we have not observed any inhibition of growth or acid production by indoleacetic acid in cultures of such variegated organisms as *Streptococcus faecalis*, *Lactobacillus arabinosis*, *Staphylococcus aureus*, *Proteus vulgaris*, *Acrobacter aerogenes*, and *Escherichia coli*, except when rather high concentrations of indoleacetic acid were employed. Then, however, the inhibition was not alleviated by niacin or tryptophane. These facts, coupled with the failure of indoleacetic acid to stunt the growth of almost half the rats in the study of Kodicek and associates,²⁸ warrant considerable caution in evaluating the role of this compound in the etiology of pellagra.

The final thread in this story, to date, is the observation of Raska³¹ that administration of 0.4 Gm. of adenine plus sodium phosphate per day to dogs on a good, standard laboratory ration induced the development of a blacktongue-like syndrome accompanied by a moderate hypertension in as little as one week, the animal dying after fourteen days. Until this observation is coupled with a therapeutic or prophylactic trial of niacin, tryptophane, or even whole liver substance and until some data are available concerning the quantitative distribution of adenine in foodstuffs, it will not be possible to determine the significance of this observation in the etiology of pellagra. However, this finding well may be of far-reaching fundamental significance, and further investigation should certainly be prosecuted vigorously.

Therefore, it appears that pellagra, as it occurs endemic among a corn-eating population, is a disease involving the metabolic interrelationships of niacin, pyridoxine, tryptophane, indoleacetic acid, perhaps adenine, and at least one other unidentified toxic substance, to say nothing of the effects of the numerous other vitamin and amino acid deficiencies and general level of protein intake

associated with such a diet. Which, if any, of these factors other than the niacin is involved in the development of the fatal acidosis and dehydration of the crises of blacktongue and pellagra, as seen on a corn diet and the mode of action of niacin in this connection, remains obscure. Despite these many gaps in our comprehension of the pathogenesis of pellagra, to Harriette Chick⁴⁰ must go credit for what now seems the first proper formulation of pellagra; she states that "Pellagra is caused by a toxic substance derived from the maize diet, which can be corrected by sufficient 'good' protein or perhaps by sufficient vitamin B₃ (which is found to accompany the 'good' proteins)."

That corn is not essential to the pathogenesis of classical pellagra long has been known and has been described in epidemic proportions among the inhabitants of a Japanese prison camp⁴¹ who were living on a diet high in carbohydrate (on a percentage basis) but low in calories, protein, sources of the B complex and entirely lacking animal protein. The pellagra was complicated by nutritional edema and beriberi, in contradistinction to the dehydration of pellagra seen among corn eaters, and consisted mainly of extensive lesions of the skin and the mucosa of the gastrointestinal tract. In this connection it is well to note that there exists, as yet, no correlation between the known physiologic and chemical mechanisms involving niacin and its derivatives and the integrity of the skin and mucosa. Nor is there any explanation for the observation that exposure of the skin to sunlight not only results in an exacerbation of the dermatitis but of the systemic manifestations of pellagra as well.⁴² The pathogenesis of the Chittenden-Underhill syndrome^{43, 44} needs further study. This syndrome which occurs in vitamin A-deficient pups may actually bear no etiologic relation to blacktongue and may be simply another expression of the disturbed "integrity" of mucosal and epithelial structures usually found in vitamin A-deficient animals. In this case it is manifest as an infection of the mouth with Vincent's organisms as also has been found in niacin deficiency blacktongue⁴⁵ but, perhaps for entirely different reasons.

A few other unsolved problems of niacin metabolism also may be worth mentioning. No explanation is available for the fact that niacin administration results in an elevated red cell concentration of the pyridine nucleotides while nicotinamide administration does not.^{46, 47} This seems even more puzzling, considering the vitamin action of nicotinamide, the existence of nicotinamide and not the acid in the coenzyme molecules, and the fact that the tissue (including erythrocytes) enzyme which destroys these nucleotides does so by cleaving nicotinamide as such from the remainder of the molecule,⁴⁸ a reaction which is inhibited by the presence of nicotinamide but not niacin.^{49, 50} In contrast, it is nicotinamide which has been reported to prevent cobalt-induced polycythemia in rabbits.⁵⁰ No information is available concerning the effects of niacin in this connection nor of the effects of niacin, niacinamide, cobalt, or combinations thereof on the pyridine nucleotide concentrations of red cells in this species. While niacin and niacinamide distribute themselves equally between erythrocyte and plasma water,⁴⁷ red cells show a considerable avidity for N¹-methylnicotinamide, the erythrocyte concentration of the latter remaining considerably

elevated long after the plasma concentration has returned to normal following intravenous administration.⁵¹

Najjar and associates⁵³ have proposed that it is the methylated pyridinium form of niacin which may be the physiologically active form of the vitamin. They claim to have demonstrated antiblacktongue activity for N¹-methylnicotinamide in dogs and also to have treated successfully a hamster, moribund in nicotinic acid deficiency.⁶⁰ (It may be noted parenthetically that other workers have failed thus far to produce nicotinic acid deficiency in the hamster.) This hypothesis was furthered by the report of Vanece⁵⁴ describing amelioration of dermatitis and glossitis in a case of pellagra on treatment with N¹-methylnicotinamide. However, since the psychomotor disturbances in this patient apparently became even more severe after this treatment and since the patient had previously been given 20 mg. of nicotinamide, it is not possible to evaluate properly this report. More recently, Najjar and Deal⁵⁵ have claimed to demonstrate demethylation of N¹-methylnicotinamide by estimating its lipotropic activity in choline-deficient rats. However, the variable activity they obtained undoubtedly can be ascribed more properly to the diminished appetite of such rats; this, indeed, has been found to be the case in this laboratory.⁵⁶ The minute excretion of nicotinamide and nicotinic acid in the urine of these rats after eating diets containing 1 and 2 per cent of N¹-methylnicotinamide easily may have been due to impurities in the N¹-methylnicotinamide preparation. At any rate, useful demethylation does not appear to be a major metabolic pathway for this compound. Since this substance possessed no antiblacktongue activity when tested in the Wisconsin laboratory,⁵⁵ there is, as yet, little reason to believe that the methylated form of nicotinamide is the biologically active structure, although the methylation of nicotinamide yet may be found to serve a physiologically "useful" role. Further work also is required to elucidate the physiologic significance of the oxidation of N¹-methylnicotinamide to the corresponding 6-pyridone.⁵² No physiologic role has been ascribed to unbound niacin (that is, niacin not present as part of the pyridine nucleotides) which has been found in significant concentration only in the liver and whose concentration does not drop markedly even in animals dying of niacin deficiency, while that of the pyridine nucleotides is drastically reduced. This problem may be resolved by more accurate determinations of pyridine nucleotides in fresh liver.

NITROGEN BALANCE

PHILIP HANDLER, PH.D.
DURHAM, N. C.

STUDIES of nitrogen balance have been made in countless physiologic and pathologic conditions. The scheme given herein, while obviously inadequate, is offered as a framework for the consideration and interpretation of such data.

The proteins referred to are the tissue proteins in general. While one might consider the liver proteins to be most important, it has been amply demonstrated that in hemorrhagic shock there occurs a liberation of amino acids from the proteins of skeletal muscle.¹ The processes involved in reactions 1 and 2 are but little understood. Nevertheless, the classical work of Schoenheimer and colleagues² has left no doubt that this interchange is of a rapid, dynamic, and constant nature heretofore totally unrealized. There must exist a host of factors which influence the rate, extent, and equilibrium point of such reactions. Reason does exist to suspect that these reactions do not necessarily entail complete degradation and resynthesis of the tissue protein molecules. A deficiency of a single essential amino acid, even in the adult expected to be in nitrogen equilibrium, would suffice to maintain the equilibrium in favor of reaction 2 since there is no reason, at present, to suspect the synthesis of a protein molecule lacking any one of its normal constituent amino acids. Interruption of endocrine control (the anterior pituitary) perhaps may shift the reaction toward amino acid accumulation as may also excessive adrenocortical or thyroid activity, while excessive pituitary function and testosterone administration in both sexes increase nitrogen retention and protein accumulation. Since the reactions involved in protein synthesis are endergonic it should be expected that any disturbance of intracellular energy metabolism, the simplest being anoxia, would also interfere with protein synthesis and result in accumulation of amino acids. All told, the mechanisms involved in reactions 1 and 2 and the physiologic factors governing them await considerable investigation.

Reaction 3 represents the reversible formation and degradation of non-protein materials. There are only a few known examples of this type, such as glutathione, and they may be ignored in the remaining discussion. Reactions 4 and 5 represent the reversible oxidative deamination and transamination of amino acids. Again, the exceedingly rapid and constant rate of these reactions has been demonstrated by Schoenheimer and colleagues. However, the succeeding steps, urea formation (reaction 6) and ultimate CO₂ production (reaction 14), are not reversible. Any process which accelerates either of these reactions will automatically accelerate the other as reaction 5 then is no longer possible. The increased demands for energy or glucose formation imposed by such conditions as total inanition, partial caloric starvation, and diabetes may be regarded as examples of negative nitrogen balance due to acceleration of reaction 11. These

conditions may be under nervous or endocrine control or may be simply the result of driving a reaction "to the right" by removing one of the end products. No circumstance is known in which one can definitely attribute negative nitrogen balance to increased urea synthesis, although this remains a possibility in some forms of negative nitrogen balance resulting from trauma, and in fasted animals after administration of adrenocortical extract. However, were such a situation to arise it could, perhaps, be demonstrated and alleviated temporarily by administration of purine drugs (caffeine, theobromine) which inhibit urea formation by way of the ornithine cycle but not the glutamine mechanism.⁵

Fig. 1.—The over-all outlines of nitrogen metabolism.

Reaction 7 is the irreversible formation of nitrogenous derivatives of amino acids, that is, melanin, adrenalin, histamine, creatine, sarcosine, choline, β -alanine, carnitine, pyrrol compounds, purines, pyrimidines. It may be assumed that when these substances are formed the carbon skeletons of the essential amino acids from which they are derived are irretrievably lost for purposes of protein synthesis. In the same fashion the synthesis of nonessential amino acids from essential precursors (cystine from methionine, tyrosine from phenylalanine), reaction 8, also results in the irreversible loss of the essential amino acids involved. The apparent resynthesis of essential amino acids from nonessentials via reactions 8, 10, and 5 does not occur since, of course, entirely different α -keto acids are involved.

While little is known of the factors involved in positive nitrogen balance, there seems little reason to believe that it is the consequence of the complex phenomena necessary to dam reactions 4, 7, 8, etc. It would seem more reasonable to consider positive balance the result of a displaced equilibrium of reactions 1 and 2, perhaps with the growth hormone of the anterior pituitary as the dominant controlling factor. Again, no definite evidence is available

to decide whether this operates by decelerating protein hydrolysis (reaction 2) or accelerating its synthesis (reaction 1). However, the studies of Schoenheimer suggest that consideration is necessary only of altered reaction rates as both processes are in constant flux in young growing animals as they are in adults.

Negative nitrogen balance has been observed in many different circumstances. The situation to be considered first is that in which an adult subject is offered a diet more than adequate in all known respects but completely lacking protein or amino acids. The nitrogen excretion in adult human beings under such circumstances has been variously estimated at .025 to .04 Gm. per kilogram per day (2 to 4 Gm. per adult) of which a relatively small fraction is urea nitrogen. This value, then, represents the daily obligatory nitrogen loss and is the resultant total of all the obligatory irreversible reactions involved in the previously mentioned scheme. It is identical with what Folin termed endogenous nitrogen, although the endogenous-exogenous concept is invalid under all other circumstances.² It is not possible to determine to what extent the urea excretion is simply the consequence of reactions 4 and 6 or whether it is largely due to reactions 7, 8, 9, etc. The low rate of urea excretion suggests that the latter possibility is the more likely.

The second situation is the negative nitrogen balance associated with a deficiency of a single essential amino acid. It is obvious that in a serious deficiency of this sort no new protein synthesis is possible, as incomplete proteins are unlikely, and the bulk of the dietary nitrogen so provided would be discarded in the urine in various forms but largely as urea. However, there then still exists an obligatory metabolism of the missing amino acid. It is readily available from reaction 2. Some of that amino acid must then be metabolized via the paths of reactions 4, 7, 8, and 11. But, as a result, the other amino acids originally present in the protein from which this "catabolized" amino acid was derived are no longer useful for protein synthesis and are in consequence degraded and discarded. The extent of negative nitrogen balance is, therefore, far greater than that due to the loss of the nitrogen in the missing amino acid alone.

Were this description of the situation complete, negative nitrogen balance in single amino acid deficiencies should never be greater than that seen in the total protein deficiency previously discussed. In the latter situation the amount of nitrogen lost should be determined by that amino acid whose obligatory metabolism is greatest. Such data are not available yet for the ten possible deficiencies in order to determine which acid is the limiting factor, and this will be possible only when carefully controlled determinations are performed using the same subjects for all deficiencies. The same subjects also should undergo complete protein deficiency on an otherwise adequate diet, and in each case sufficient time must be allowed for the new equilibrium to be attained as the adjustment to a new "plane of protein nutrition" appears to be a rather slow process. However, reason does exist to suspect that the negative nitrogen loss amino acid deficiencies than in total protein depriva-

tion. While many other examples may exist in the literature, two may be taken from recent publications. Thus, it has been found that the addition of 6 per cent gelatin or a tryptophane-free fibrin hydrolysate to a diet containing 9 per cent casein actually markedly depressed the growth of young rats to a level below that on the basal 9 per cent casein diet.⁴ Growth was restored to its original level by the further addition of tryptophane (or nicotinic acid), seemingly indicating that an increased total amino acid ingestion also increased specifically the tryptophane or nicotinic acid requirement. The failure of tryptophane plus gelatin to increase the growth rate above that on the basal diet is taken to indicate another amino acid as the limiting growth factor. Earlier, Jackson and associates⁵ considered the rat growth inhibition occasioned by the addition of gelatin to a high casein diet, the result of a toxic property of gelatin, since growth could not be restored by addition of the amino acids known to be lacking in gelatin. This does not appear to be the case in the work with fibrin hydrolysates and further work is required before the status of gelatin can be certain. Similarly, Kornberg,⁶ investigating the nutritive requirements for granulocyte production in the rat, found that the addition of methionine and tryptophane to a basal gelatin diet actually increased the mortality rate from 25 to 90 per cent in a four-day test period. Reasoning from these two examples, then, it seems not unlikely that, in like fashion, single deficiencies may induce a greater nitrogen loss than that of total protein deprivation. If this proves to be true, no mechanism for the phenomenon is yet available. The situation, however, is analogous to that long known to investigators of B complex deficiencies, namely, that single vitamin deficiencies (such as thiamine) result in a more dramatic weight loss and earlier deaths than do diets devoid of all members of the B complex. The physiologic factors involved in such deficiencies may be elucidated by more complete investigation of the mechanisms involved in the toxicity of single amino acids, virtually all of which are lethal when fed or given parenterally in large quantities.²¹

Few quantitative data are available concerning the extent of nitrogen loss in human single amino acid deficiencies. Tryptophane and lysine deficiency resulted in a maximum daily negative balance of about 4 Gm. each of nitrogen,⁷ while valine and methionine deficiencies resulted in maximum daily nitrogen losses of 2.9 and 1.6 Gm., respectively, per day.⁸ No quantitative data were included in the report that deficiencies of threonine, leucine, isoleucine, and phenylalanine also result in negative nitrogen balance.⁹ All these were tested on healthy adult male subjects on a diet providing approximately 3,000 calories and 7 Gm. of nitrogen per day. It is noteworthy that, thus far, no deficiency of a single amino acid has occasioned a nitrogen loss greater than that of total protein deprivation, although it should be added that these all have been relatively brief experiments. It will be of interest to learn the extent of nitrogen loss in the other possible deficiencies as well as the effect of increasing the total nitrogen intake. The failure of histidine deficiency to evoke a nitrogen loss under similar conditions in the same subjects⁹ seems surprising in view of the high histidine content of globin and the rapid turnover of erythrocytes.

The third commonly observed situation involving negative nitrogen balance is that occasioned by various forms of trauma, such as burns, fractures, surgery, hemorrhage, and even complete bed rest. The nitrogen lost here is excreted largely as urea. (The loss through weeping exudates may be disregarded.) No critical data yet have been obtained to determine the underlying basis for this phenomenon, nor is there necessarily a common mechanism; however, until proved otherwise it is helpful to consider it of the same origin as the so-called toxic destruction of protein associated with acute infectious states. By and large, the nitrogen loss appears to be proportional to the severity of the trauma or infection although there have been numerous exceptions reported. These negative balances have been quite refractory to parenteral or dietary protein. Instead, the administration of the equivalent of about 15 Gm. of nitrogen (as protein or an amino acid mixture) has usually resulted in an almost equivalent increment in urinary nitrogen excretion. However, protein therapy has proved most beneficial during convalescence from such injuries.

Considering, then, the various possibilities in the scheme, reaction 2 seems a definite possibility in view of the marked increase in blood amino acids found in hemorrhagic shock.¹⁰ This perhaps might be occasioned either by moderate tissue anoxia or direct adrenocortical control. It is noteworthy that anterior pituitary growth hormone does not prevent or diminish the negative nitrogen balance observed in rats with fractured femurs.¹¹ The possibility of tissue anoxia does not seem significant in subjects with bone fractures or those who were simply put to complete bed rest. However, here the atrophy of the *immobilized* limb cannot be disregarded, and whatever may control this situation, it cannot be stated whether the total negative nitrogen balance observed after fractures is any greater than that of the injured member itself, a phenomenon which also may occur on a small scale in all the skeletal muscle of the subject during complete bed rest.

Excessive urea production as the initial basis of negative nitrogen balance has not been demonstrated. If it does occur, it could be demonstrated by purine administration. When the latter depresses urea excretion, a rise in the blood concentration and urinary excretion of amino acids should be expected when excessive urea synthesis itself is not the primary malefactor. Nor has any great demand for glucose or fat synthesis after trauma been observed while the administration of glucose in febrile states has not diminished appreciably the nitrogen loss.

Reactions 7 and 8 remain untested and likely possibilities. Should trauma occasion an increased irreversible production of some substance, X, from an essential amino acid precursor, this would be tantamount to the production of a single amino acid deficiency. The extensive negative balances of burned subjects have been rather refractory to parenteral or dietary protein therapy. If negative balance were caused by such a physiologic rather than nutritional essential amino acid deficiency, then it might be presumed that equilibrium could not be restored by providing total protein equivalent to that lost as urea but only by meeting the unusual requirement for the particular amino acid in question.

Only one amino acid, methionine, has been so tested and it was found effective in reducing the negative balance of burned rats on a low protein diet by Croft and Peters.¹² Increasing the dietary protein level also prevented negative balance, even though the increased protein supplied only one-third as much methionine as the minimum effective supplement of free amino acids. The nitrogen loss in these animals was not as dramatic as that in burned human beings and also differed in that the situation provoking nitrogen loss in burned human beings is refractory to protein therapy for a considerable period after the accident. Moreover, this effect of methionine has not been confirmed in burned rats and human beings by other investigators^{13, 22} including those in this laboratory.¹⁴ Nevertheless, the theoretical significance and clinical potentialities of such therapy certainly warrant a complete investigation of this and the other essential amino acids in like fashion.

It is noteworthy also in this connection that those investigators who have sought the minimum level of protein intake which would maintain the adult in nitrogen balance usually have thought that cannibalism would be the ideal situation in that this would most nearly provide an amino acid mixture of the desired proportions. While this may yet prove true for the growing animal, it is not true necessarily of the adult since there is no evidence to indicate that the pattern of obligatory daily amino acid destruction represented by reactions 4, 6 to 9, and 11 to 14 in anywise resembles quantitatively the relative concentrations of the amino acids of the tissue proteins. For this reason, the relative proportions of the dietary amino acids for optimum nutrition in infants and children may bear little resemblance to adult maintenance requirements.

The nature and locus of the action of endocrine control of nitrogen metabolism are now entirely obscure. Certainly, further investigation of the role of the anterior pituitary, adrenal cortex, thyroid, and gonads is warranted. The possibility of nervous control has received comparatively little attention. A clue of great potential significance is offered by patients with brain injuries who have been observed by neurosurgeons to develop perforating gastric and duodenal ulcers within twenty-four hours of the brain accident. It has been well established that prolonged ingestion of low protein diets results in the development of gastric and duodenal ulcers in laboratory animals,¹⁵⁻¹⁹ and Somervell²⁰ has called attention to the high incidence of duodenal ulcers in the population in the south of India which subsists on an extremely low protein ration. It seems possible, therefore, that such injured patients may develop a fulminating protein deficiency which in turn leads to the ulceration.* Such ulcers are not uncommon in burned patients as well and liver damage in the latter also has been found, perhaps again indicating the possibility of an induced specific amino acid deficiency. This situation might also provide a bridge between the biochemical factors (gastric acidity, pepsin, protein deficiency), the physiologic factors (action of the vagus, pylorospasm), and the unquestionable psychogenic factors in ulcer formation.

*This possibility arose in conversations with Dr. J. S. Harris, with whom studies of this situation are now in progress.

LABORATORY METHODS

ASSAY OF PENICILLIN, STREPTOMYCIN, TRIVALENT ORGANIC ARSENICALS, AND OTHER BACTERICIDAL AND BACTERIOSTATIC AGENTS

A TECHNIQUE BASED ON AN ORIGINAL APPLICATION OF MATHEMATICAL PRINCIPLES
WITH ADAPTATIONS FOR ALL ASSAY PURPOSES

EDWIN E. OSGOOD, M.D.
PORTLAND, ORE.

WITH THE TECHNICAL ASSISTANCE OF BARBARA GAMBLE, B.S.

A SIMPLE, rapid, accurate, flexible technique for assay of antibacterial agents has been described elsewhere.¹ In the same article nomographs are published permitting determination of results of the assay by inspection. Also in this article are given the details of the materials and equipment needed and references to previously published assay methods.

The present article is written for those investigators who wish a full understanding of the mathematical basis for the calculation, an outline of its adaptability for various purposes, an idea of the accuracy attainable by each of these adaptations, and an understanding of the effects of the various variables investigated in the course of developing the method.

Foster and Woodruff² reviewed the penicillin assay methods available and formulated certain criteria for an "ideal" method. While many assay methods have been published since the date of this excellent review, none have generally displaced those in use in 1943. The investigation herein described was initiated in an attempt to meet the requirements of these authors.

THE PRINCIPLE OF THE METHOD

Our observations have shown that:

1. The growth of bacteria in culture of the type used in these experiments is directly proportional to the change in optical density of the culture.
2. The optical density can be read directly on the Klett-Summerson colorimeter (scale is $= 500 \times$ optical density).
3. An accurate growth curve can be plotted using scale readings directly from the Klett-Summerson colorimeter (1 division $= 20,000,000$ colonies per cubic centimeter).
4. The tangent of the angle between the straight-line growth curve of a control and of antibiotic-containing culture is directly proportional to the antibiotic concentration under the conditions specified.

From the Division of Experimental Medicine, Department of Medicine, University of Oregon Medical School.

Aided by a grant from John C. Higgins.

The penicillin and streptomycin used were made available by the Food and Drug Administration of the Federal Security Agency, E. R. Squibb & Sons, New York, N. Y., The Upjohn Company, Kalamazoo, Mich., and Abbott Laboratories, North Chicago, Ill. The trivalent organic arsenicals were supplied by Abbott Laboratories.

Received for publication, Sept. 3, 1946.

5. This tangent can be determined from the difference in turbidimetric readings which occurs with time in each culture during the straight-line phase of growth. Therefore, only one control and one known concentration of penicillin are needed to determine many unknowns, and a determination is possible before the difference in turbidimetric readings between the control and penicillin-containing cultures is statistically significant.

When, at a later time, the difference in turbidimetric readings between the control and penicillin-containing cultures is statistically significant, this difference is proportional to the square root of the penicillin concentration; therefore, the computation may be made by both methods if desired.

STANDARD TECHNIQUE

This permits assay by each of two methods on the same sample. All techniques are described for penicillin assay first, since only minor modifications are necessary for assay for streptomycin, trivalent organic arsenicals, or other antibiotics. All manipulations are made with sterile tuberculin or 5 c.c. Luer syringes and 26 gauge needles through 70 per cent alcohol on vaccine vial caps. The 0.85 per cent NaCl used for dilutions and the bactotryptose phosphate broth for the cultures are kept in sterile vaccine vial-capped containers. All photoelectric turbidimetric readings are made with the Klett-Summerson photoelectric colorimeter, using a No. 66 filter, on a 5 c.c. volume in the vaccine vial-capped colorimeter tubes for this instrument. All concentrations, unless otherwise specified, refer to the concentration per cubic centimeter in this 5 c.c. volume. The organism found most suitable for the test is the Oregon-J strain of *Staphylococcus aureus* obtainable from the American Type Culture Collection* by request for No. 9801 or from the National Collection of Type Cultures† by request for No. 6982. After incubation until growth has reached the proper turbidity, keep the inoculated culture in an ice bath in the refrigerator. It is usable for a week.

The following photoelectric colorimeter readings are made:

- A = the broth blank on each new lot of bactotryptose broth
- B' = the culture blank on inoculated broth before placed in the ice bath; should be checked just before use each day
- B' - A = turbidity due to bacterial growth in the broth culture and should be 12 to 15; 15 corresponds to a colony count of 300,000,000 per cubic centimeter

Set up a control, a known, and as many unknown photoelectric colorimeter tubes as desired, as shown in Table I. The known should contain 0.04 unit of penicillin per cubic centimeter corresponding to the addition of 0.5 c.c. of a 0.4 unit per cubic centimeter dilution of a standard penicillin preparation. Concentrated unknowns should be diluted to an estimated concentration of 0.2 to 0.4 unit per cubic centimeter and 0.5 c.c. used. On each of these tubes in rapid sequence take the following readings:

*Georgetown University, Washington, D. C.

†The Lister Institute, London, England.

- B: at 0 time just before putting tubes in the 37 degree water bath;
this is the culture blank
C: 1.5 hours after incubation is started
D: 2 hours after incubation is started
E: 2.5 hours after incubation is started
F: 4 to 30 hours after incubation is started, usually the next morning

Reading D may be omitted except when unusually high concentrations are anticipated or the earliest possible result is desired. Reading B is necessary only when unknowns differ widely in turbidity or color. During the interval between Readings B and C, the cultures are in the lag phase of growth, the growth curves are not straight line, and there is little antibiotic action.

$D - C = y_1$, the turbidity due to bacterial growth during the first half hour of straight-line growth

$E - D = y_2$, the turbidity due to bacterial growth during the second half hour of straight-line growth

Ideally, y_1 and y_2 should be equal.

$E - C = y_3$, the turbidity due to bacterial growth in the first hour of straight-line growth, $= y_1 + y_2$

The figure usually used in the calculation by Method 1 is y_3 .

$F - B =$ turbidity due to bacterial growth called corrected F, and the difference between corrected F for the control and for each of the antibiotic-containing cultures is called y_4

This is the figure used in calculation by Method 2. Data are recorded as shown in Table I.

TABLE I. DATA OF TYPICAL EXPERIMENT

		TUBE 1—CONTROL (C.C.)		TUBE 2—KNOWN (C.C.)		TUBE 3—UNKNOWN (C.C.)	
Add							
0.85% NaCl		0.5		—		—	
0.4 U. per c.c. Nu penicillin		—		0.5		—

*In the 37° C. water bath.

THEORY OF THE CALCULATION

Note that area I in Fig. 1 shows the growth curves of a control and a penicillin-containing known or unknown of a typical experiment. Area II is an enlargement of the indicated portion of area I with a relative increase in scale

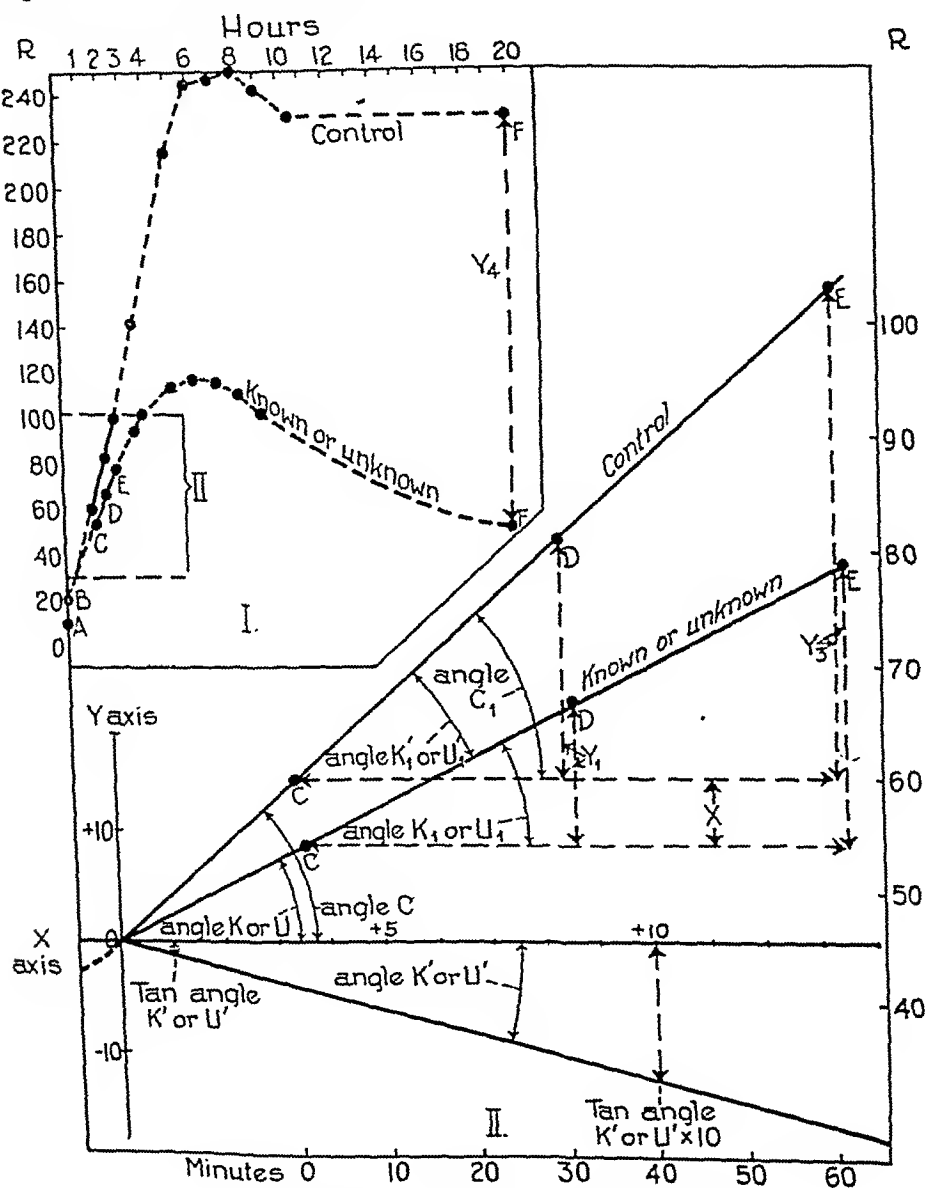

Fig. 1.—Explanation of the theory of the computation.

on the X axis to separate the curves for greater clarity. R refers to photoelectric colorimeter readings. The time scale for area I is in hours; for II it is in minutes, with the 0 beginning at the time of Reading C. In a typical experiment this is 1.5 hours after the tubes were placed in the 37° C. water bath, but

it may be any time while growth is straight line. A, B, C, D, E, and F are, respectively, the photoelectric colorimeter readings for the broth blank, the culture blank, the three readings during the 1-hour period used in the calculation for Method 1, and the final reading at 18 to 24 hours used in the calculation by Method 2. Note in the enlarged area II that the straight-line growth curves of the control and penicillin-containing known or unknown separate at the point marked 0, where the Y and X axis are drawn to intersect, and that prior to this, as indicated by the curved dotted line, the growth is not straight line and there is no difference in turbidity between the control and the penicillin-containing cultures. Note that y_1 is the difference between the colorimeter reading, D, of the control or penicillin-containing culture and its reading, C, 30 minutes earlier, and that this forms one side of a right triangle with the time interval, X, of 30 minutes, or 5 units on the X axis forming the other side and the growth curve the hypotenuse. The same is true for the difference, y_3 , between the Readings C and E, except that here the value of X is 1 hour or 10 units on the X axis. Therefore, the value of y_1 divided by the corresponding value of X is the tangent of the angles C_1 or of K_1 or U_1 . Since parallel lines intersecting a straight line form equal angles, angle $C_1 =$ angle C and angle K_1 or $U_1 =$ angle K or U. By inspection it is evident that angle C is the angle which the control makes with the X axis and angle K or U is the angle which the penicillin-containing culture makes with the X axis. It is apparent that y_1 or y_3 divided by the corresponding values of X give the tangents of C_1 , K_1 , or U_1 and hence of C, K, or U. Note further that while the Readings C, D, and E are taken later for the penicillin-containing known or unknown than for the control, this time lag does not alter the value of the tangents so long as the growth curves are still in the straight-line phase. Note by inspection that angle C - angle K or U = angle K'_1 or U'_1 , the angle at which the penicillin-containing culture leaves the control culture. By construction, angle K' or $U' =$ angle K'_1 or U'_1 . This construction is equivalent to making the growth curve of the control coincide with the X axis and rotating the growth curve of the penicillin-containing culture through an equal arc. The tangent of angle K' or U' then is a measure of the rate at which the growth curves of the antibiotic-containing cultures are deviating from the growth curve of the control culture.

This method of computation allows for differences in effectiveness of the antibiotic agents with differences in growth rate. It has been found, as shown by the results reported in Tables IV to VI for Method 1, that the tangent of the angle between the growth curves of the control and the known or unknown cultures is directly proportional to the antibiotic concentration for the antibacterial agents so far tested. Because it is so inconspicuous in the diagram at the point where $x = +1$, the numerical value of $10 \times \tan K'$ or U' also is shown in Fig. 1 at the point where $x = +10$.

The calculation by Method 2 is based on the observation that the square root of the penicillin concentration is proportional to the difference between the photoelectric colorimeter readings due to turbidity from bacterial growth of the control culture and the penicillin-containing culture after 4 to 6 hours of incubation. Since this difference increases with time, computations by this method

increase in accuracy as long as the difference increases. Computation by Method 2 may be useful at 3 to 6 hours if inadvertently a higher concentration of penicillin was introduced than intended and the y_1 readings were already beyond the straight-line phase.

CALCULATION

An example of the calculation is given in Table II.

Method 1.—Let x = time in 0.1 of an hour or 6-minute intervals and y = the difference between Readings D or E and Reading C in the same tube.

$$\tan C = \frac{y}{x} = \frac{y_1}{5} \text{ or, } \frac{y_2}{10}$$

TABLE II. CALCULATION FROM DATA IN TABLE I*

	TUBE 1 CONTROL	TUBE 2 KNOWN	TUBE 3 UNKNOWN
<i>Method 1</i>			
1.5 to 2 hours			
y_1	21	13	16
Tangent = $\frac{y_1}{5}$	4.2 = tan C	2.6 = tan K	3.2 = tan U
Angle from tan table	76.6° = C	69.0° = K	72.7° = U
C - K or U		7.6° = K'	3.9° = U'
Tangent from tan table		0.1334 = tan K'	0.0682 = tan U'
$\frac{\tan K'}{40} = m$		$\frac{0.1334}{40} = 0.003335$	
$\frac{\tan U'}{m} = \text{units} \times 1,000$			$\frac{0.0682}{0.003335} = 20.5$
1.5 to 2.5 hours			
y_2	43	25	32
Tangent = $\frac{y_2}{10}$	4.3	2.5	3.2
Angle from tan table	76.9°	68.2°	72.6°
Angle C - K or U		8.7°	4.3°
Tangent from tan table		0.1530	0.0752
$\frac{\tan K'}{40} = m$		$\frac{0.1530}{40} = 0.003825$	
$\frac{\tan U'}{m} = \text{units} \times 1,000$			$\frac{0.0752}{0.003825} = 19.6$
<i>Method 2</i>			
y_4		180	120
$f = \frac{y_4}{6.325\ddagger}$		$\frac{180}{6.325\ddagger} = 28.46$	
$\sqrt{z} = \frac{y}{f}$			$\frac{120}{28.46} = 4.216 = \sqrt{z}$
$z = \left(\frac{y}{f}\right)^2 = \text{units} \times 1,000$			$4.216^2 = 17.8$
<i>Summary</i>			
Theoretical units			0.0200
Method 1 with y_1			0.0205 = + 2.5%
Method 1 with y_2			0.0196 = - 2.0%
Method 2			0.0178 = -11.0%

*In practice, since the position of the decimal point in the final result is evident by inspection, the decimal points may be ignored; however, it is necessary to carry the operations to four significant figures if the full accuracy of the method is to be attained.

†It is usually more convenient to express results in hundredths of a unit and divide by $2 = \sqrt{4}$, that is $\frac{180}{2} = 90$, $\frac{120}{90} = 1.333$, $1.333^2 = 1.78$ hundredths of a unit = 0.0178 units per cubic centimeter.

when C is the angle which the control curve makes with the X axis, y_1 is Reading D - Reading C for the control, and y_2 is Reading E - Reading C. Determine the tangents of growth curves of each known (K) and unknown (U) from the appropriate readings on these tubes in precisely the same manner.

Look in a tangent table* and find the values for the angles C, K, and U corresponding to tans C, K, or U.

Angle C - angle K = angle K' and angle C - angle U = angle U', the angles between curves of the control and each penicillin-containing culture.

From a tangent table obtain $\tan K'$ which is directly proportional to the amount of penicillin. Therefore, $\tan K'$ divided by the units of penicillin in the known expressed in thousandths is a constant, m.

In the example given, 0.04 unit penicillin was used in the known. The factor for calculation of the unknowns is found from:

$$\text{Concentration in thousandths of units} = m \tan K',$$

hence,

$$m = \frac{\tan K'}{40}$$

The concentration of penicillin in the unknowns can now be determined by substitution of $\tan U'$ for each unknown for $\tan K'$ in the previously mentioned equation.

Multiply by the dilution of the unknown for the value in the original material.

ALTERNATE METHOD OF CALCULATION WITHOUT USE OF TANGENT TABLES

From the trigonometric formula for the tangent of the difference of two angles it follows that:

$$\frac{\tan C - \tan K}{1 + \tan C \cdot \tan K} = \tan K'$$

and

$$\frac{\tan C - \tan U}{1 + \tan C \cdot \tan U} = \tan U'$$

The following is an example using data for $\frac{y_2}{10}$ from Tables I and II for tans C, K, and U:

$$\frac{4.3 - 2.5}{1 + 4.3 \cdot 2.5} = \frac{1.8}{1 + 10.75} = \frac{1.8}{11.75} = 0.1532 = \tan K'$$

$$\frac{4.3 - 3.2}{1 + 4.3 \cdot 3.2} = \frac{1.1}{1 + 13.76} = \frac{1.1}{14.76} = 0.0745 = \tan U'$$

$$\frac{0.1532}{40} = 0.00383$$

$$\frac{0.0745}{0.00383} = 19.5 \text{ thousandths of a unit per cubic centimeter.}$$

*Lange, N. A.: Handbook of Chemistry, ed. 6, Sandusky, Ohio, 1946, Handbook Publishers, p. 198 (appendix, mathematical tables, and formulas); or see other handbooks or trigonometry texts.

Method 2.—Subtract the corrected Reading F for the known penicillin solutions and for the unknowns from the corrected Reading F of the control, Tube 1. Call this difference y_4 . Let z equal the concentration of penicillin in the colorimeter tube in hundredths of a unit per cubic centimeter. The difference in reading is directly proportional to the square root of the concentration. Therefore, Equation 1 expresses the relationship between y and z , when f is a factor, usually between 60 and 120, corresponding to the y_4 value for 0.01 unit of penicillin per cubic centimeter and depending on the initial inoculum, the susceptibility of the organism, and the rate of growth.

$$\text{Equation 1: } y_4 = f \sqrt{\frac{z}{100}}$$

Determine the factor f by substituting the known concentration of penicillin (z) expressed as hundredths of units and the corrected colorimeter difference reading, y_4 , in the Equation 1 and solving for f . After f has been determined, substitute the y_4 readings for each unknown and solve for the concentration z . A sample calculation is given in Table II.

Modifications for Special Purposes.—The technique previously described is suitable for the determination of penicillin in solution, in cerebrospinal fluid, in urine, and in *Penicillium notatum* cultures. Slight modifications are necessary for determination in blood serum, ascitic fluid, or pleural fluids and for greatest accuracy in urine and *P. notatum* cultures. The computation is the same for all, except that the dilution factor varies.

Directions for Blood Serum: Record the time of the last administration of penicillin. Separate the serum from a 5 to 10 c.c. blood sample collected in a rubber vial-capped centrifuge tube twenty to ninety minutes after the last dose of penicillin. Record the time of collection.

Into Tube 1, place 0.5 c.c. of sterile saline and 0.5 c.c. of the serum of the patient, taken just before dose of penicillin, or clear serum from a healthy person who has not been receiving neoarsphenamine or other trivalent organic arsenicals; into Tube 2, place 0.5 c.c. of standard penicillin solution and 0.5 c.c. of the same serum used in Tube 1; into Tubes 3, 4, 5, etc., place 0.5 c.c. of saline solution and 0.5 c.c. of each unknown serum. Add to each 4.0 c.c. of the broth culture.

If values below 0.1 unit per cubic centimeter are anticipated, it is better to use 1.0 to 2.0 c.c. of the serum and 3.5 or 2.5 c.c. of inoculated broth and to multiply by a dilution factor of 5.0 or 2.5 instead of 10 to get the units in the unknown serum.

Directions for Cerebrospinal Fluid: These are the same as for solutions of penicillin, except that larger quantities may be necessary if the concentration is low, and dilutions may be necessary if the concentration is high.

Directions for Pleural or Ascitic Fluid: Centrifugate and, if grossly purulent, pass the supernatant fluid through a Seitz filter to clarify and sterilize. Then proceed as for blood serum.

Directions for P. notatum Cultures: Make an accurate dilution of the centrifugated or Seitz-filtered* medium, so that the estimated content in the final broth culture will be approximately 0.04 unit per cubic centimeter and will certainly lie between 0.01 and 0.1 unit per cubic centimeter. Use uninoculated equally diluted *P. notatum* medium for the control and known penicillin tubes and proceed as for penicillin solutions.

MODIFICATIONS OF TECHNIQUE

Certain simple adaptations of the standard technique previously described have been found useful and are herein listed. All procedures follow this standard technique except as noted. Results shown in Tables III to VI are consecutive and unselected and include normal routine manipulative errors. Dilutions were made with unselected tuberculin syringes.

For Maximum Simplicity.—Carry out all incubations in an incubator. Omit all readings except Reading F at 4 to 30 hours, preferably 18 to 24 hours, after start of incubation. Compute by Method 2 only, using nomograms.¹ Accuracy for a single reading is about ± 25 per cent, as shown by examples in Table III.

For Earliest Possible Result.—After 1-hour incubation read, at 15-minute intervals, Readings C, D, and E. Calculate by Method 1 on basis of first half-hour period in which the successive 15-minute readings on the same tube agree within two points and differ from control by more than two points. Results are given in Table IV. Note that accuracy is much less at low concentrations, but the readings may be continued to follow the standard technique.

For Routine Technique.—Take Readings C and E at the beginning and end of any 1-hour period, beginning between 1.5 and 3.5 hours after the tubes are placed in the water bath. Results are shown in Table V. Accuracy of a single determination is about ± 10 per cent.

To simplify laboratory procedure, inoculated broth may be introduced into the culture tubes by a pipetting machine and micropipettes or drops from calibrated needles utilized for introduction of concentrated samples.

*Accuracy in middle range is intermediate between routine technique and technique for maximum accuracy.

For Maximum Sensitivity to Low Concentrations.—Use Oxford *Staph. aureus* strain H. Insure that inoculum gives $B' - A$ reading of 10 to 12 or less and that the known contains a final concentration of 0.008 unit per cubic centimeter of standard penicillin. Results are shown in Table VI.

For Maximum Accuracy.—Determine the approximate concentration. Dilute, with precision-calibrated glassware, all unknowns to a calculated final concentration of 0.04 unit per cubic centimeter. Run control, known, and each unknown in quadruplicate, using the standard or routine technique and average results.

Our results by this method agree within ± 5 per cent. Duplicate determinations on standard penicillin agreed within ± 2.5 per cent with one control, one known, and three replicate unknowns. Inspection of the 0.04 unit per cubic centimeter block of Table V will indicate the results available by any number of replicate determinations in this concentration range.

For Maximum Range.—Use a series of knowns ranging in final concentration by 0.02 unit steps from 0.2 to 0.02 unit per cubic centimeter and by 0.002 unit steps from 0.01 to 0.002 unit per cubic centimeter. Use as knowns the nearest higher and lower concentrations, compute by both Methods 1 and 2, and average the results.

Our experience has shown that the concentration by Method 2 is more accurately given by the relation

$$y_4 = f \sqrt{z} - b$$

where b is an arbitrary constant. To utilize this formula, two knowns are needed. The following example illustrates the method of determination of constants:

For 0.040 unit per cubic centimeter
For 0.010 unit per cubic centimeter

$$\begin{aligned} y_4 &= 192 \\ y_4 &= 84 \end{aligned}$$

Expressing concentration z in hundredths of units and substituting these values,

$$(1) \quad 192 = f\sqrt{4} - b$$

$$(2) \quad 84 = f\sqrt{1} - b$$

Subtracting (2) from (1) $108 = f$.
Substituting $f = 108$ in equation (1) or (2).

$$b = 24$$

Hence, in this example, $y_4 = 108 \sqrt{z} - 24$. Results routinely obtained by this method of computation are shown in Table VI.

TECHNIQUE FOR STREPTOMYCIN ASSAY

The method is equally satisfactory for streptomycin assay. The only modifications necessary are the use of two knowns containing streptomycin and making Reading F for Method 2 at 4 to 6 hours instead of the next day.

Knowns are prepared with a final concentration of 1 unit ($1 \mu\text{g}$) and 3 units ($3 \mu\text{g}$) per cubic centimeter. Calculation by Method 1 is identical with that described for penicillin.

If Method 2 is used, the concentration is *directly* proportional to the y_4 difference in colorimeter reading; hence,

$$y_4 = f z$$

when z is the streptomycin concentration in units per cubic centimeter. If it be desired to read the streptomycin cultures the next day, a known of 10 units per cubic centimeter must be used. Nomograms¹ may be used for calculation.

The effective range for streptomycin is 0.2 to 20 units per cubic centimeter in the final culture. Sensitivity may be increased for low concentrations by the use of up to 50 per cent serum and correspondingly less broth culture medium.

TECHNIQUE FOR TRIVALENT ORGANIC ARSENICALS

The trivalent organic arsenicals used in the treatment of syphilis have been shown³ to be very effective antibacterial agents against all strains of staphylococci investigated, as well as against hemolytic streptococci, some strains of *Hemophilus influenzae*, and many strains of *Streptococcus viridans*. Therefore, the method herein described may be used for the assay of any of these trivalent organic arsenicals. The technique for Method 1 is identical with that for penicillin or streptomycin and for Method 2 it is the same as that described for streptomycin, since the y_4 differences are directly proportional to the concentrations. The ideal concentration of the known for both methods with neoarsphenamine is 1.5 μg per cubic centimeter in the final culture. The ideal concentration for mapharsen is 0.75 μg per cubic centimeter. For the other trivalent organic arsenicals, the activity against bacteria is proportional to the arsenic content relative to that of neoarsphenamine,³ so that knowns for these should be so diluted that the final culture contains 0.3 μg per cubic centimeter of arsenic. The effective range for neoarsphenamine is from 0.2 to 3.0 μg per cubic centimeter; therefore, unknowns should be diluted to an estimated concentration of 2 to 30 μg per cubic centimeter when 0.5 cubic centimeter is used with 4.5 cubic centimeter of broth culture.

DETERMINATION OF SERUM LEVELS OF ANTIBACTERIAL AGENTS DURING THE ENTIRE TIME PERIOD BETWEEN DOSES

Except when antibacterial agents are given by continuous drip, a single serum level does not indicate the concentration at any time except the moment when the blood was taken. However, the levels at other times may be roughly computed by the factors given elsewhere.¹ They can be accurately determined by making two determinations an hour or two apart, the first one 30 minutes to an hour after administration of the drug. Using the equal interval scale for time and the logarithmic scale for concentration, plot on polycyclic semilog graph paper these two points and draw a line through them. For the trivalent organic arsenicals, follow the same procedure, plotting the results on log log paper. The serum levels at any time after the initial mixing may now be read directly from the graph.

TECHNIQUE FOR QUANTITATIVE BACTERIOLOGIC STUDIES

It seems possible that this technique could be used equally well for quantitative studies of the effects of any variable on bacterial growth, and the results would be available quickly instead of having to wait for colony counts and with far greater accuracy than colony counting technique affords. Growth could be stopped at any desired stage and quantitative studies made on the medium.

THE EFFECTS OF VARYING THE INOCULUM

Any clear, fluid, bacteriologic medium may be used if light transmission is not too low. Hartley broth gives even more satisfactory results, and because it does not contain dextrose might be preferable in testing *P. notatum* cultures which may contain notatin. The baetotryptose medium was selected because it was readily available and easily prepared, is more or less standard in composition, is already buffered, and gives very rapid growth to high turbidity. Double- or triple-strength baetotryptose broth gave no better results than the standard-strength broth. Addition of serum does give better results than the standard-strength broth. One per cent and 2 per cent baetopeptone broth gave slower growth to lower turbidities. The faster the growth, the more uniform its rate, and the higher the final turbidity, the better are the results with penicillin; and the slower the growth, the greater is the sensitivity to streptomycin. For penicillin y_3 values of 30 to 70 are satisfactory, and for streptomycin y_2 values of 20 to 50 are satisfactory. Still better media no doubt can be discovered.

THE EFFECT OF VARYING THE INOCULUM

These effects are shown graphically in Fig. 2 for penicillin. The lower the inoculum, the slower is the start of the straight-line phase of growth, the more rapid is the final growth rate attained, the more sensitive is the technique for low concentrations, the more accurately do the penicillin effects correspond to the equations, and the greater are the y_4 and tangent differences per unit concentration of penicillin. However, with low inocula, a slight difference in the size of the inoculum or the blank reading of the colorimeter tube introduces a much greater error in the result, and the range for high concentrations of penicillin is reduced by early cessation of growth. Inocula corresponding to a $B' - A$ reading of 30 or over are unsatisfactory because of small differences in growth rate with large differences in penicillin concentration. For most purposes an inoculum corresponding to a $B' - A$ reading of 12 to 15 is most satisfactory.

THE EFFECTS OF VARYING THE STRAIN OR SPECIES OF ORGANISM USED

Much more work needs to be done on this. The ideal organism for routine use should be only moderately sensitive to penicillin action, should grow rapidly to high turbidities, should show no tendency to produce variants, and should remain in the straight-line phase of growth for a long time on simple and inexpensive media. The Oregon-J strain of hemolytic *Staph. aureus* more nearly fulfills these requirements than any other organism so far tested and is very satisfactory also for streptomycin and trivalent organic arsenicals. The strain of

beta hemolytic streptococcus investigated did not grow to high enough turbidities or rapidly enough; the Oxford *Staph. aureus* strain II, while slightly superior for very low concentrations of penicillin, did not stay in the straight-line phase of growth long enough and ceased growth at a turbidity reading of 200 versus 250 for the Oregon-J strain. The National Institute of Health's strain 209 P had the same defects as the Oxford strain H; however, it was not as sensitive to low concentrations, although it was more sensitive than the Oregon-J strain. Other strains of staphylococci, strains of *Bacillus subtilis*, and pneumococci have been investigated and were found unsuitable.

Fig. 2.—Effects of variations in size of inoculation on growth curves of the control and penicillin-containing cultures.

THE EFFECTS OF VARYING THE TIME OF READINGS

As may be seen from Fig. 2, the longer the interval between readings used in the computation by Method 1, the smaller the relative error in the photoelectric colorimeter readings, but the greater the error due to departure of the growth curve from a true straight-line curve, especially with high concentrations. The 1-hour period is best for the entire range, but a half-hour period is best for concentrations above 0.06 unit per cubic centimeter with the Oregon-J strain. Too early initial readings introduce error by including a part of the lag phase of penicillin action or of the prestraight-line growth curve, and too late readings introduce error by including nonstraight-line portions of the growth curves. With the standard technique and the Oregon-J strain, growth is essentially straight line from $1\frac{1}{4}$ to 4 hours with concentrations below 0.06 unit per cubic centimeter and departs least from a straight-line curve between 1.5 and 3.5 hours.

In calculation by Method 2, y_4 differences increase in significance and reliability rapidly from 3 hours, when they first become significant for high concentrations, to 6 hours and then slowly until 17 hours, after which they change very little in the next 24 hours.

THE EFFECTS OF VARYING THE TIME SCALE

The reason for choosing 6-minute units is that it brings the tangents into a convenient part of the tangent table and involves dividing by 10, which is merely pointing off a decimal place. It is not important that these be exact 6-minute units; equally accurate results are obtained if the time interval is somewhat shorter or longer than an hour and 10 is still used as the divisor, provided that the time interval between readings is the same for each tube.

THE EFFECTS OF VARYING THE FILTER

Any filter may be used, but the advantages of the No. 66 filter are that it transmits red and yellow light very well, giving a low blank that is little affected by the yellow colors of the medium, penicillin solutions, blood serum, urine, or the red colors of slightly hemolyzed serum. For certain research purposes, where very low concentrations are to be determined, a green No. 54 filter is preferable, since it gives a higher difference for small changes in turbidity; however, the blanks will be higher with this filter. Still greater accuracy was obtained with the blue No. 42 filter and Hartley broth, but the bactotryptose broth gives too high a blank A reading.

USE OF OTHER PHOTOELECTRIC COLORIMETERS

The principle of the method is applicable directly to any photoelectric colorimeter having a logarithmically spaced scale and can be adapted to other types

by the formula* $(2.000 - \log_{10} T) \times 500 \times \frac{12}{\text{inside tube diameter in mm.}} =$

reading on Klett-Summerson instrument. However, the Klett-Summerson instrument is strongly recommended because of the convenient size of the tubes, the large number of scale divisions, the great rapidity with which readings may be made, and the high accuracy without sacrifice of range.

COMPARISON WITH OTHER METHODS

In comparing the results in the tables with those of other methods, it is important to remember that these† are results on a single unknown, when many unknowns were determined from a single control and a single known; whereas the results reported for most methods are the averages of several replicates or dilutions of an unknown compared with a series of controls and knowns.

*When $(2.000 - \log_{10} T)$ is the formula for deriving optical density from per cent transmission (T), and 12 mm. is the inside diameter of the Klett-Summerson tube. The Klett-Summerson scale is calibrated in divisions $500 \times$ optical density.

†Except results in Table VI which are based on two knowns.

SUMMARY

A quantitative method of penicillin assay is described which is flexible enough to compare favorably with any published method in simplicity, sensitivity, accuracy, range, specificity, and speed with which results are available.

It is based on turbidimetric determination, using a new principle of computation.

It is adapted to all types of penicillin assay now made and to quantitative assay of other potent bacteriostatic or bactericidal agents. Techniques for streptomycin and trivalent arsenicals are given.

The method has the advantage of employing materials and supplies already available in most laboratories and techniques with which the average laboratory technician is familiar. Results of plus or minus 25 per cent accuracy may be available within 2 hours and of plus or minus 10 per cent accuracy within 2.5 to 3 hours. For most applications there is no interference by penicillin-resistant contaminants. It will detect as little as 0.001 unit per cubic centimeter of penicillin with plus or minus 100 per cent accuracy. When performed for maximum accuracy, error can be reduced below plus or minus 5 per cent. It will cover a fourfold range with plus or minus 10 per cent accuracy, a sixfold range with plus or minus 25 per cent accuracy, and a hundredfold range with plus or minus 100 per cent accuracy at the extremes.

AN EXPERIMENTAL METHOD FOR OBTAINING AN ULTRAFILTRATE OF THE BLOOD

M. R. MALINOW* AND W. KORZON

CHICAGO, ILL.

ULTRAFILTRATION may be a useful approach to the investigation of simultaneous clearances with the kidney and in the study of bound and unbound blood constituents. Ultrafiltration permits extraction of a true ultrafiltrate¹ and can be considered as analogous in principle to glomerular filtration. Geiger² has described an ingenious device consisting of two layers of collodion supported by two perforated metal sheets that he connected to the carotid artery of a dog. The blood was circulated between the collodion layers and an ultrafiltrate extracted. It is possible that an improved ultrafilter may have some merit, when properly developed, as a supplement to the excretory function of the kidney.

Our purpose was to develop an ultrafilter which could duplicate glomerular function in a dog, both qualitatively and quantitatively, to be used in an attempt to prolong the life of uremic animals. We decided to use cellophane tubing as the filter membrane, as it appears to have advantages over other materials used in the past. Recent reports have shown that it has a very reproducible and consistent porosity, that sterilization does not greatly alter its permeability, that it has a neutral reaction, and that it can withstand high pressures when properly supported.³⁻⁶ From a practical standpoint cellophane tubing is inexpensive, is available in several thicknesses and diameters, and is relatively easy to handle.

We have constructed an apparatus which permits the flow of blood from an animal through cellophane tubes arranged to provide a maximal filtering surface per unit volume of blood. To increase the rate of water and crystalloid extraction, the cellophane tubes are submitted to an effective filtering pressure of approximately 800 mm. of mercury. This equipment has been successful in collecting the ultrafiltrate of circulating blood in quantities up to 1,200 c.c. per hour.

DESCRIPTION OF THE APPARATUS

The apparatus consists of a filter, a vacuum chamber, and a pump to circulate the blood. These are illustrated in Figs. 1 to 8 and details are given in the legends.

The Filter (Figs. 1 to 4).—The filter is made up of twenty identical filter tubes connected in parallel. Each filter tube consists essentially of a flat cello-

phane tube* passed between two strips of nylon tape† which are sewed together down their full length. This is then sandwiched between two stainless steel strips which are held together by a slotted clamping bar on each side. Filtering pressure is obtained by placing the completely assembled filter tube in a vacuum chamber, bringing the blood inlet and outlet tubes out through a seal, rather than by subjecting the blood to an increased positive pressure.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

Figs. 1 to 4.—Details of the filter: A cellophane tube (18) 21.4 mm. in diameter and 0.02 mm. in thickness is passed between two strips of nylon tape (21), which are sewed down their full length on both sides so as to form a continuous tube over the cellophane. A short piece of cellophane tubing (17) is passed over each end of the previous one. Two flanged stainless steel connections (12),* with their rubber tubes (14), are passed through holes previously pierced in the cellophane tube. A thin rubber gasket (19) is placed over the flange of each connection, and the latter are then screwed to a stainless steel strip (5) with a washer (13) and a nut (11). This strip has two holes in it, 11 mm. in diameter and 83.9 cm. apart, for the purpose. Each end of the cellophane tube is closed with two stainless steel bars (9 and 15) with a rubber gasket (16) between them. These bars are fastened with two screws (10). Another strip (8), of the same width as (5) but 2.8 cm. shorter, is placed under (5) and both are inserted into the slots milled in the clamping bars (6 and 7). Holes (20), 1 mm. in diameter, at intervals of 9.5 cm. permit the drainage of the filtrate.

*Between the flange of the connection (12) and the cellophane tube (18) there is a space, not shown in Figs. 2 or 3, through which the blood finds its way when it circulates within the filter.

The principle of the filter is simple. The cellophane tube through which the blood circulates acts as a semipermeable membrane. It is separated from the steel strips by the nylon tape which, by virtue of its weave, forms a porous chamber through which the vacuum can act to reduce the pressure on the exterior of the cellophane tube.

*Manufactured by Visking Co., Chicago, Ill.

†Kindly supplied by Phoenix Trimming Co., Chicago, Ill.

The capacity of each filter tube is 30 c.c., but this can be reduced by placing filter paper strips of appropriate thickness between the nylon tape and the steel strips. The filtration surface of each unit is 400 sq. cm., approximately. Under a filtering pressure of 800 mm. Hg and with a blood flow between 15 and 100 c.c. per minute, about 60 c.c. of ultrafiltrate per hour are obtained. If more ultrafiltrate is desired, several filters like the one described may be used in parallel (Fig. 5) connected by a collector tube. If the filter is to be used without

Fig. 5.—Twenty filter tubes connected in parallel with the collector tubes (1), by which blood is distributed to and collected from them. The tube (2) serves as an inlet or outlet for the blood in the whole filter. The filter tubes are clamped to an aluminum frame (3 and 4) with the metal strips and screws (5 and 6).

Fig. 6.—The apparatus assembled and ready for use. A, A single filter unit; B, the vacuum chamber; C, the blood pump; D, the vacuum pump; E, the rheostat; F, the bottle for collecting the ultrafiltrate; G, a mercury manometer connected to the vacuum chamber. The inlet tube (1) is connected through a wide cannula (2) and a three-way stopcock (3) to the femoral artery of the dog; (4) is the special rubber tubing used in the blood pump; (5) is the stopper with two tubes; (6) is the tube through which blood is pumped into the filter; (7) is the tube connected with the mercury manometer; (8) is the inlet tube to the filter; (9) is the outlet tube from the filter; (10) is the outlet tube from the chamber, leading to (11) an ordinary condenser used to warm the blood before being returned to the animal through tube (12). This latter tube also has a three-way stopcock and a cannula. This cannula is connected with the femoral vein of the animal. The bottle (F) receives the ultrafiltrate from the chamber through a rubber tube (13) and is also connected to the vacuum chamber by another tube (14). Other tubes (15 and 16) carry warm water to and from the condenser.

Fig. 7.—The large vacuum chamber employs a brass cylinder, 122 cm. in length, 25.3 cm. in inside diameter, and 3 mm in thickness. The metal tubes (1) of 8.5 mm. bore are slightly smaller than the rubber tubes (2) (Fig. 5, 2), in order to provide a perfect seal when the chamber is evacuated. The aluminum plates (3) seal the ends of this chamber with the rubber gasket (4) and are tightly held in place with the rods (5) and nuts (6). A tube (7) drains the ultrafiltrate into the collector bottle (8). Another tube (9) connects with the vacuum pump (not shown). The two supports (10) differ in height to permit the ultrafiltrate to drain toward the filtrate collecting tube (7).

Fig. 8.—The pump consists of two semicircles of plated iron (1) between which the special tube (2), a rubber tube with a side piece of rubber that is held by the iron semicircles, is fastened with four screws (3). Rollers (4) milk the tube causing the blood to circulate. Gears (5) connect the axis of the roller arm with the motor (6).

circulation of blood or when a small amount of blood is to be ultrafiltered, the outlet tube is clamped after the filter has been filled.

The Vacuum Chambers (Figs. 6 and 7).—Two vacuum chambers were used. For use with one or two filter units a long glass tube was employed, which was sealed by a rubber stopper at each end. A glass cannula through each stopper provides a connection for the inlet and outlet tubes of the filter unit, and two more cannulae supply a means of exhausting the tubes and of collecting the ultrafiltrate.

The large chamber, for use with up to twenty filter tubes, is a large diameter brass tube closed at each end by an aluminum disk with a rubber gasket. A seal for the rubber inlet and outlet tubes of the filter is formed by drawing each through a short metal tube which is soldered into the body of the brass tube. The inside diameter of these tubes was made slightly smaller than the outside diameter of the rubber tubing to insure a good seal. Another tube soldered into the brass tube connects with a collector bottle for the ultrafiltrate.

The Blood Pump (Fig. 8).—This pump, similar to the one described by DeBaker,³ consists essentially of two semicircles of plated iron, one on top of the other, between which a special rubber tube* is clamped. Two rollers, driven by an electric motor, through a worm gear, milk approximately 2 c.c. of blood through this tube in each revolution. Among the advantages of this type of pump are that a nonpulsating flow is obtained and that there is little trauma to the blood cells.

TECHNIQUE IN ASSEMBLING THE EQUIPMENT†

The technique in assembling the equipment must be followed rigorously for successful results. A length of cellophane tubing is cut from the roll and is passed between the strips of nylon tape, leaving an extra 15 cm. of cellophane on each side. Two short pieces of cellophane tubing are opened‡ and placed over the ends of the longer tube to re-enforce it at these points. A dusting of starch powder is used to permit the short pieces to slide easily. The long tube is opened and a hole is punched near each end and on the same side of the cellophane tube with a special punch, 11 mm. in diameter, the same distance (83.9 cm.) apart as the holes in the strip (5). In order to make these holes, an ordinary wooden tongue depressor is introduced into the long tube and the punch is pressed against it through the double cellophane. The stainless steel connections (12) with their rubber tubes are passed through these holes, a thin rubber gasket (19) is placed above the cellophane, and the connections (12) are screwed tightly to the strip (5); then both ends are closed by tightly screwing the two bars (15 and 9) together with a rubber gasket (16) in between. The strip (8) is placed below and both strips are introduced into the slots of the clamping bars (6 and 7).

*Obtained from A. S. Aloe Co., St. Louis, Mo.

†The numbers refer to Figs. 1 to 4.

‡Dry cellophane tubing is opened by applying a small strip of adhesive or transparent tape to each side of the flat cellophane tube about 1 cm. from the end, allowing the tape to project a little beyond the tube. The strips of tape are then pulled gently apart, thus separating the cellophane layers at the end of the tube. Blowing into the tube at this point will then open the tube down its entire length.

The unit so assembled is soaked in cool tap water for half an hour and then is checked for leaks by connecting one of the rubber tubes (14) with a source of air under approximately $1\frac{1}{2}$ atmospheres of positive pressure. The patency of the filter is checked first by watching the escape of air from the second rubber tube. If the filter is not patent, the air is shut off and turned on again, increasing the pressure slowly. If this does not open the filter, injection of saline with a syringe may accomplish the purpose.

Leaks in the system are manifested by small bubbles coming out while air is injected under pressure with the outlet tube clamped off. These must be differentiated from trapped air in the system. Trapped air disappears after a time but air from a leak continues to escape. There are three sources of leaks:

1. Holes in the cellophane, which were found in one out of ten tubes of cellophane employed by us. Such leaky tubes must be replaced.

2. Inadequate tightening of the connections (12) or of the end clamps (15). A continuous stream of air bubbles locates the loose connection, and these leaks usually disappear after retightening.

3. Wrinkles in the cellophane at the ends (17). Under these conditions air continues to escape despite retightening. In such cases removing the end pieces (15) and smoothing out the cellophane generally corrects the leakage.

The connections (12), all rubber tubing, glass cannulae, and adaptors used in the experiment, were rendered pyrogen-free by boiling for thirty minutes in 4 per cent NaOH, rinsing with tap water, boiling for fifteen minutes in 0.5 per cent acetic acid, and finally rinsing again with tap water.

CHARACTERISTICS OF THE FILTER TUBE

In order to determine its characteristics, a filter tube was placed in the glass vacuum chamber and the inlet and outlet tubes each were connected with a graduated bottle containing citrated human blood. Altering the relative height of the two bottles changed the pressure and the rate and direction of blood flow. Further pressure and flow changes were obtained by using a screw clamp on the outlet tube.

Filtration under the same conditions was performed with two filter tubes which were identical except that the capacity of one was 15 c.e., the other 30 c.e. The filtration rates of both were the same. Nevertheless, when a large number of units are used in parallel, the total amount of ultrafiltrate is sometimes less than would be obtained if the same number of units were functioning separately. The probable reason for this is that, as the resistance of a large number of filter tubes in parallel is very low, with a relatively small blood flow (up to 150 c.e. per minute for 20 units) some of the tubes are not supplied with circulating blood and so do not function.

No change in the filtration rate was observed: (1) as a result of sterilization* with steam at 250° F. for fifteen minutes; (2) with continued filtration

*Sterilization was performed by connecting the inlet of the filter with a pressure cooker after the desired temperature and pressure was attained and clamping the outlet of the filter.

over ten hours; (3) with blood flow varying from between 15 and 100 c.e. per minute; and (4) with ultrafiltering liquids of different viscosity (namely, blood, and saline solution).

The blood used in filtration was examined microscopically on a number of occasions after centrifuging, and no hemolysis was observed.

Using a vacuum of 35 mm. Hg and varying the positive pressure applied to the circulating blood, the following results were obtained in the same filter:

EFFECTIVE PRESSURE IN MM. HG	FILTRATION RATE IN C.C. PER HOUR
760	54
760	56
780	60
805	60
825	60
825	59
875	63
925	70

The filtration rate was 5 c.e. per hour in another experiment in which only 75 mm. Hg of positive pressure was applied and no negative pressure was used.

As expected, these observations show that there is a proportionality between the pressure and the amount of ultrafiltrate formed.

NATURE OF THE ULTRAFILTRATE

The ultrafiltrate obtained from human blood and that of dog blood were analyzed in several instances for urea, nonprotein nitrogen, and proteins. It was found to be protein-free and with the N.P.N. and urea in equilibrium with the blood. In later experiments employing dogs certain other ultrafiltrate constituents were analyzed and the results are shown in Table I.*

ACTION OF THE ULTRAFILTER WHEN CONNECTED TO A DOG

Method.—Two types of experiments were performed. In the first type, a single ultrafilter tube was connected with a normal dog. In the second, the large unit with 20 such units in parallel were connected with a nephrectomized, uremic dog. For the latter type of experiment the dogs were bilaterally nephrectomized three days previously; they were injected daily with 100 c.e. of 50 per cent solution of glucose intravenously and with 100 c.e. of 5 per cent glucose, 50 c.e. of saline, and 50,000 units of penicillin subcutaneously. Blood volume determinations were made at the beginning and at the end of the experiment. Blood samples were taken immediately before and once daily after the nephrectomy, at the beginning of the experiment, one hour afterward, and at the end. Samples of the ultrafiltrate were taken simultaneously with the blood collections during the filtration. Chlorides, urea N, creatinine, CO₂ capacity, proteins, glucose, and hematocrit were determined in some of these samples. The

*The methods used were: urea nitrogen: Ormsby, A. A.: J. Biol. Chem. 146: 595, 1942; proteins: Weichselbaum, T. E.: Am. J. Clin. Path. 16: 40, 1946; creatinine: Folin, O., and Wu, H.: J. Biol. Chem. 38: 81, 1919; chlorides: Wilson, D. W., and Ball, E. G.: J. Biol. Chem. 79: 221, 1923; carbon dioxide capacity: Van Slyke, D. D., and Cullen, G. E.: J. Biol. Chem. 30: 289, 1917; blood volume: single samples in duplicate twelve minutes after injection of the dye (T1824); hematocrit: 10,000 r.p.m. during ten minutes in Winthrobe tubes. These determinations were carried out in the Department of Biochemistry through the kindness of Dr. C. Cohn.

TABLE I. OBSERVATIONS ON MALE DOG, WEIGHT 27 POUNDS, RENDERED ANEPHRIC AND CONNECTED TO ULTRAFILTER*

REMARKS		UREA N (MG./100 C.C.)	CREATININE (MG./100 C.C.)	PROTEIN (MG./100 C.C.)	CO ₂ (VOL. %)	HEMATOCRIT (%)	Cl (MG./100 C.C.)
Preoperative	Blood	21		6.9	45	48	630

After 8 hr. of filtration	Blood	75		3.9		39	640
	Plasma	83	6.0				600
Ultrafiltrate obtained at end of 1 hr.		160	7.2				660
Ultrafiltrate obtained at end of 8 hr.		80	5.0				660
		BEFORE FILTRATION			AFTER FILTRATION		
Plasma volume		964 c.c.			1010 c.c.		
Blood volume		1550 c.c.			1650 c.c.		
Hematocrit		38%			39%		

Total amount of filtrate, 7,200 c.c. collected in eight hr.

Total amount of urea N "excreted," 6.9 Gm.

Urea clearance (concentration in the blood assumed to be 125 mg./100 c.c., the mean between 175 and 75), 11.3 c.c./blood/minute.

*In this experiment the lag seen in Fig. 9 and explained in the text has not been taken into consideration. This lag explains the lack of parallelism between the plasma and ultrafiltrate concentrations of urea and creatinine.

samples collected after one hour represent the results of the mixing with the donor's blood in the filter and the result of one hour of filtration. Fluid balance during the filtration was maintained by injecting intravenously every ten minutes an amount of Ringer-Krebs solution* equal to the amount of ultrafiltrate collected during the interval.

In both types of experiment the inlet of the filter was connected with the central end of the femoral artery and the outlet with the central end of the femoral vein, the blood being circulated by means of the pump† previously described. The effective filtering pressure used was approximately 800 mm. of mercury. The dogs were injected with 40 to 50 mg. of heparin‡ immediately before the experiment to prevent blood coagulation and were narcotized with morphine, with a 1 per cent solution of procaine used locally.

In order to help avoid the formation of clots the cannulae used were as large as possible. They were washed with concentrated nitric acid before the experiment, cleaned with 4 per cent NaOH, and then rinsed in tap water. The system was filled with saline when only one or two filter tubes were used and with compatible dog's blood when more units were employed, in order to avoid air embolism and the possibility that the dog would lose too much blood into the filter. The blood was warmed to body temperature before it was returned to the animal.

*The Ringer-Krebs solution was prepared by mixing the following substances in 100 c.c. of water: NaCl, 6.923 Gm.; KCl 0.354 Gm.; CaCl₂, 0.057 Gm.; KH₂PO₄, 0.170 Gm.; MgSO₄·H₂O, 0.2925 Gm.; NaHCO₃, 2.10 Gm.; Glucose, 1.0 Gm.; O₂ was bubbled through and the temperature was maintained at approximately 38° C.

†With a single filter tube the pump is not always necessary, as the normal arterial pressure is sufficient for the purpose.

‡Liquaemin liberally supplied to the department by Roche Organon, Inc., Nutley, N. J

Results With Normal Dogs.—Seven normal dogs were subjected to filtration with a single unit for periods ranging from one to five hours. The flow of blood through the filter was 50 to 70 c.c. per minute. All of the animals survived.

Uniformly, the amount of filtrate collected was 60 c.c. per hour, it was always protein-free, and in no case was hemolysis detected macroscopically. The concentration of urea in the blood and in the ultrafiltrate of one typical experiment is shown graphically in Fig. 9. As can be seen, there is a period of forty minutes during which the filtrate shows little urea concentration. This is due to the dilution of the ultrafiltrate by the saline held in the nylon tape. As this saline is replaced by ultrafiltrate, the urea concentration rises sharply and then levels off. The difference between the concentration of urea in the filtrate and that in the plasma may indicate that urea is not wholly diffusible or that it is bound. This possibility now is being investigated.

Fig. 9.—A typical experiment performed on a normal dog, showing the urea N concentration in the plasma and in the ultrafiltrate. The arrow indicates the beginning of filtration.

Several deductions can be drawn from these experiments:

1. The filter yields an appreciable amount of ultrafiltrate when connected with a dog.
2. The filter itself is not toxic. The dogs survived the experiment for a long time, and when they were sacrificed, autopsy revealed no macroscopic abnormalities. The limb used was in good condition despite the ligation of the femoral artery and vein.

Results With Uremic Dogs.—Four uremic dogs were used in the second type of experiment. The blood flow through the filter was 110 c.c. per minute with each. Two dogs died accidentally after two and three hours of filtration, respectively; the first died from shock due to blood loss, the second from pulmonary embolism. The other two dogs were filtered successfully for three and eight hours, respectively. They did not appear to be injured by the filtration,

judging from the general appearance and pulse rate, and were up and around when they came out of the anesthesia. These animals died in uremia thirty-six hours after the completion of the experiment. A typical result in one of these dogs is summarized in Table I.

These experiments show that the animals apparently were not adversely affected by the procedure, despite the fact that as much as 7,200 c.c. of fluid was filtered from the blood of a dog (and replaced by Ringer-Krebs solution) with a blood volume of 1,550 cubic centimeters. The chlorides returned to the normal level and the hematocrit remained constant during the experiment. Urea and creatinine were reduced by this ultrafiltration. Nevertheless, the fact that only 7 Gm. of urea were cleared in eight hours makes this procedure with the apparatus employed unsuitable for man, even though its use in dogs may considerably reduce the blood urea. A larger ultrafilter with more filtering surface, or one employing a much greater filtering pressure, may have a sufficient clearance of urea for man, but the dialyzer described by Kolff appears superior in simplicity and in obtainable results because the steeper gradient between urea concentration in the blood and the outside fluid dialyzed into seems to produce a greater urea clearance per unit area of cellophane than the ultrafiltration method described.

CONCLUSIONS

An ultrafilter employing cellophane is described and its applicability for experimental purposes noted.

The filter described has definite advantages over previous ones because of the following reasons:

1. It provides a large amount of ultrafiltrate in comparison with the volume of blood of the animal.
2. The blood in the filter can be placed under a wide range of pressures and can be circulated within the filter at different rates without the red blood cells being unduly traumatized. The filter does not lead to macroscopic hemolysis of the blood.
3. It is easily sterilized.

This ultrafiltration method, however, has limitations in its use for the control of uremia, especially since it has such low clearance values compared with the values reported by Kolff^{13, 14} for dialysis.

Such a filter may be useful in the investigation of simultaneous clearances with the kidney and in the study of bound and unbound blood constituents. The composition of ultrafiltrates obtained during this investigation favors this opinion.

We wish to express our gratitude to Dr. L. N. Katz for his advice and guidance and to acknowledge the considerable assistance given us by other members of the department.

BOOK REVIEWS

Penicillin in Syphilis. By Joseph Earle Moore, M.D., Associate Professor of Medicine and Adjunct Professor of Public Health Administration, the Johns Hopkins University; Physician-in-Charge, Syphilis Division of the Medical Clinic, and Visiting Physician, the Johns Hopkins Hospital; Chairman, Syphilis Study Section, National Institute of Health, United States Public Health Service; Chairman, Subcommittee on Venereal Diseases, National Research Council. Charles C. Thomas, Publisher, Springfield, Ill., 1946. Price \$7.50. Cloth with 731 pages, 109 illustrations, 122 tables.

The startling discovery of the treponemicidal action of penicillin by Mahoney, Arnold, and Harris in midsummer of 1943 resulted in the almost immediate organization of a nationwide cooperative study of the efficacy of this antibiotic in syphilis. This collaborative effort, which is perhaps unparalleled in medical history, was motivated by the urgent necessity of the Armed Forces for authoritative information regarding the effectiveness of this agent. Although the facilities of eight laboratories of experimental syphilis were enlisted for intensive study of penicillin in rabbit syphilis, time did not permit final definition of the time-dose relationship in the experimental animal before human trial was undertaken. Accordingly, clinical investigation has proceeded simultaneously in a total of forty-four clinics and treatment centers. Thus far, these participating agencies have treated some 25,000 patients with early syphilis by assigned schedules (thirty-six all told) in a uniform manner, results being analyzed as a group by a central statistical unit.

Since the outset of the study Moore in his capacity as Chairman, first of the Penicillin Panel of the National Research Council and more recently of the Syphilis Study Section of the United States Public Health Service, the sponsoring organizations, has occupied a position uniquely fitting him for authorship of this monograph. As a consequence, he has had access to material restricted during the war years, some of which still is unreported, as well as to unpublished data of the individual cooperating groups. The author thus has been able to assemble under one cover all the information relating to the effect of penicillin in syphilis available as of October, 1946.

As stated in the preface, "The author's only excuse (for this monographic presentation of the admittedly preliminary results now available*) can be that so far, the medical profession has been informed only that penicillin is of value in syphilis. How best to employ it in the several stages of syphilitic infection, on the basis of current knowledge, has nowhere yet been systematically presented. This monograph is an effort to supply the deficiency. It is prepared with full knowledge of its inadequacies and of the necessity for frequent revision to maintain it up to date."

The material is presented in nineteen chapters—actually eighteen, since one (the last) is concerned with streptomycin. Of these, the first seven are devoted to fundamental information—the chemistry of the penicillins, pharmacology, toxicity, therapeutic efficacy, etc. For the student of syphilis the author's exposition of these basic data is unquestionably of greater value than the chapters concerned with clinical use. Of particular interest is the discussion of the results obtained by the cooperating laboratories in experimental syphilis and the implications of these results as to the mode of action of penicillin against *Treponema pallidum*. The experimental data thus far available suggest, and this is not belied by the accumulating clinical results, that the *desideratum* in syphilis may not be large dosages over short periods of time but smaller dosages prolonged for weeks or perhaps even months. If these indications are borne out by further study, the hope of a quick, safe (that is, with penicillin alone) cure for early syphilis suitable for mass application may prove to be unattainable.

*Parenthetical words are the reviewer's.

One chapter is concerned with the administration of penicillin for other diseases as a source of confusion in the diagnosis of syphilis. The suppressing effect of penicillin administered for the treatment of gonococcal infections on the early manifestations of syphilis is emphasized, as is the necessity for prolonged serologic follow-up (at least four months) of penicillin-treated patients with gonorrhea, to rule out simultaneously acquired syphilis.

The remaining ten chapters recount the accumulated information pertaining to the clinical use of penicillin in the various stages of syphilitic infection. Since, from the standpoint of the Army and Navy during the war years, early syphilis and the various types of late neurosyphilis presented the greatest therapeutic problems, emphasis has been directed toward defining the place of penicillin in the treatment of these stages of the disease. The early syphilis results are those accumulated prior to August, 1945, based on the treatment of approximately 11,000 patients by twenty-six treatment regimens. At the time this book was written, patients treated since the date mentioned had been followed too short a period of time for even preliminary evaluation. The results of penicillin treatment of early syphilis may be summarized with the statement that the optimum regimen of treatment with penicillin (sodium or calcium suspended in peanut oil and beeswax), either alone or combined with metallothiopyrone, still is not defined since the over-all cumulative failure rates of even the best schedules approximate 15 per cent at the end of one year. Suggested schedules utilizing larger and/or longer dosage schedules than those so far analyzed are appended by the author who implies, though it is not so stated, that the results may be no better than with smaller amounts.

Scattered information based on small series of patients indicates that penicillin is effective in early syphilis resistant to arsenic and bismuth, in benign late syphilis, and in at least one type of ocular involvement (the iritis of early syphilis); however, in others such as interstitial keratitis and primary optic atrophy, results are only partially successful. In view of the absence of serious toxic reactions few will disagree that penicillin is the treatment of choice of the pregnant woman with syphilis and probably also of the infant with early congenital syphilis. Little or no information is available as to the efficacy of penicillin in either latent or cardiovascular syphilis since these are both long-term projects. In this respect, however, the physician is well advised that penicillin is no more effective than combined arsenical and bismuth therapy in rendering the blood test negative, since in late syphilis seroresistance is the rule regardless of the agent employed.

The discussion of penicillin in neurosyphilis reflects more than elsewhere the author's own experience, past as well as present, in the treatment of these complex syndromes. The results with penicillin, even though preliminary, demonstrate conclusively that this agent exerts a profound effect on the spinal fluid abnormalities, the improvement in these elements continuing for many months after treatment. At the present time major discussion centers around the question of whether penicillin plus fever offers any advantage over penicillin alone. Comparative data are scanty, and, although the trends of the spinal fluid syndromes presented by the author suggest that combined treatment may be slightly superior, the results for the most part are not statistically significant. Until more evidence has been accumulated many syphilotherapists will continue to regard the superiority of combined penicillin and fever as not proved; but few will disagree that for the present the combination should be recommended for the graver parenchymatous forms of neurosyphilis. There undoubtedly will be dissenters to the author's opinion that induced malaria holds any advantage over fever therapy by mechanical means.

Sufficient has been said to indicate that Moore has presented in detail the available information about the effect of penicillin in syphilis. It is to be hoped that this book will serve to correct many misconceptions regarding the use of penicillin in this disease and the results to be expected therefrom. It was inevitable that, in a few respects at least, the book would be outdated already on the day of publication. This fact does not detract from the vast fund of basic data that the book presents, and this reviewer, for one, hopes that the author's promise of frequent revision will be fulfilled.

VIRGIL SCOTT.

Diseases of the Retina. By *Herman Elwyn, M.D.*, Senior Assistant Surgeon, New York Eye and Ear Infirmary. The Blakiston Company, Philadelphia, 1946. Price \$10.00. Cloth with 587 pages, 170 illustrations, 19 in color.

The author has brought up to date the clinical picture of retinal diseases, correlating the abnormal physiology with the subjective and objective findings of the subject. The course of each disturbance is followed through the life picture of the disease. Treatment is discussed concisely from the viewpoint of the ophthalmologist, who is familiar with the closely associated fields of internal medicine and neurology.

The book is divided into eight parts: I. Diseases of the Retina Resulting From Disturbances in Circulation; II. Diseases of the Retina Resulting From Vascular Malformations; III. Degenerative Diseases of the Retina on a Hereditary Basis; IV. Inflammatory Diseases of the Retina; V. Tumors of the Retina; V. Diseases of the Retina Leading to Retinal Detachment; VII. Developmental Anomalies of the Retina; VIII. Radiation Injuries of the Retina.

The present-day concept of vascular disease per se, along with the primary vascular change occurring in inflammatory, metabolic, and degenerative diseases, has been handled extremely well. The author has followed a definite plan in presenting his material in an orderly and concise manner with the minimum expenditure of words.

This volume belongs in the library of all ophthalmologists, internists, and neurologists.

WILLIAM M. JAMES, M.D.

ANNOUNCEMENT

REVISED BIOLOGICS REGULATIONS

It is desired to call attention to a revision of the regulations governing the manufacture and sale of biologic products published in the Federal Register on Jan. 21, 1947, and effective thirty days after that date.

As is indicated in these regulations, the scope of the Biologics Law is broadened somewhat, and certain diagnostic products administered or applied to a person or prepared from or with the aid of a biologic product now should be distributed in interstate commerce only if prepared by a licensed laboratory.

Also requiring a license for distribution are blood grouping and Rh typing serums, for which minimum requirements have been prepared in anticipation of the revision of the regulations.

Information as to the status of any of these products, or the requirements applicable to them, may be obtained from the Biologics Control Laboratory, National Institute of Health, Bethesda 14, Md.

MECHANISM OF THE THYMOL TURBIDITY TEST

PHILIP P. COHEN, M.D., AND FRANCES L. THOMPSON, B.S.
MADISON, WIS.

THE thymol turbidity test of Maelagan has been shown to be of considerable diagnostic value in certain types of liver disease.¹⁻⁴ Maelagan¹ and Carter and Maelagan⁴ have reported that the test was probably associated with an increase in gamma globulin. Recant and associates,² on the other hand, have shown that the test depended on the presence of a lipid-containing fraction of serum globulin rather than the gamma globulin.

In the present study experiments are reported which show that the thymol turbidity test depends on a reaction involving chiefly the beta globulin fraction of serum.

METHODS AND PROCEDURES

Thymol Reagent and Test.—The thymol reagent was prepared essentially as recommended by Maelagan.¹ It was found that the reagent developed a turbidity on standing after seven to ten days. However, reheating, cooling, and again seeding with thymol crystals resulted in a clear solution.

Thymol turbidity values were estimated from a set of Kingsbury⁶ visual standards calibrated against known amounts of human serum albumin and sulfosalicylic acid.

Treatment of Serum With Thymol Reagent for Electrophoretic Analysis.—An aliquot of serum, usually 10 c.c., was diluted with two parts of thymol buffer, pH 7.8, and dialyzed in the cold room (2° C.) against 200 to 250 c.c. of thymol buffer, pH 7.8, for twelve hours or longer. At the end of the dialysis period the precipitate was removed by centrifugation.

The crystal clear supernatant (thymol-treated serum is consistently more translucent than untreated serum) was then dialyzed in the cold room twice against 200 c.c. of 0.1 μ sodium diethylbarbiturate buffer, pH 8.6, and finally against 1,500 c.c. of the same buffer for at least thirty-six hours. The precipitate was resuspended in a volume of 0.1 μ barbiturate buffer, pH 8.6, to give a protein concentration of between 0.5 and 1.0 per cent. The resulting turbid solution was dialyzed in the cold room against several changes of buffer and finally against 1,000 c.c. of buffer for at least thirty-six hours. High speed centrifugation (10,000 r.p.m.) for ten minutes was found effective in clarifying the solution.

Electrophoretic Analysis.—Electrophoresis was carried out at a potential gradient of about 6 volts per centimeter, at 1.5° C., using the schlieren scanning

technique of Longworth.⁷ Most of the runs were made with the single center section 11 c.c. cell. A micro cell, 2 c.c. capacity, was employed in some instances for both the thymol precipitate and the treated and untreated serum samples. A comparative study of the patterns and mobilities of the same serum with the macro and micro cells revealed close agreement in a series of ten determinations.

Relative composition of the serum samples was estimated by measuring the areas under the projected patterns after the areas were resolved into a series of symmetrical curves. In all instances the percentage composition represents the average of the ascending and descending boundaries. Mobilities were de-

terminated by measuring the migration distances from the salt boundaries. Conductivity measurements were made on the protein-free buffer used as the dialyzing solution.

RESULTS

The percentage composition of serum before and after thymol treatment is shown in Table I. In each instance the thymol turbidity value is indicated. The most striking change in the composition of the serum after treatment with thymol reagent is the decrease in the beta globulin fraction. As can be seen,

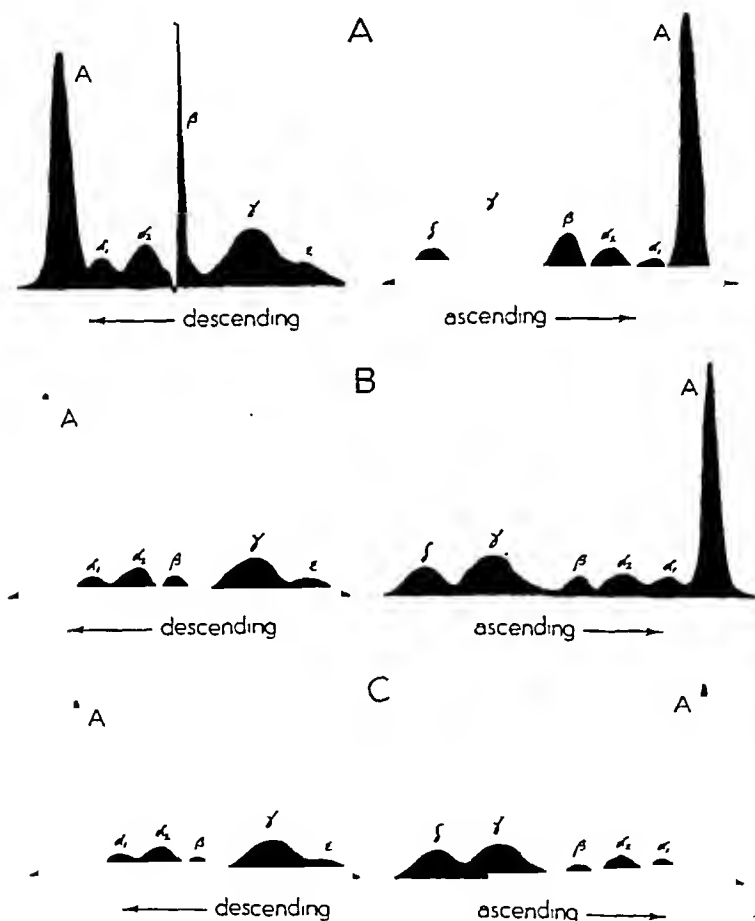

Fig. 1.—Electrophoretic diagrams of Serum 11 (Table I) before treatment with thymol reagent (A), after treatment for twelve hours (B), and after treatment for seventy-hours (C).

this fraction is decreased in all instances including the normal serum although the decrease in the latter case is small. Treatment of a thymol-negative and a thymol-positive serum for seventy-two hours instead of the usual twelve hours with thymol reagent resulted in a small additional decrease in the beta globulin percentage (Serum 11C and 12C, Table I). The average decrease in the beta globulin percentage as a result of thymol treatment is of the order of 50 per

cent. The average decrease in the percentage of gamma globulin is of the order of 4 per cent. All the other fractions show an increase, the albumin percentage being increased the most. It is apparent from these data that the beta globulin fraction is the only fraction of serum showing a striking change as a result of thymol treatment. The electrophoretic diagrams of Serum 11 (Table I) before and after treatment with thymol reagent are seen in Fig. 1. The disappearance of the beta anomaly after thymol was seen in all instances.

Fig. 2.—Electrophoretic diagrams of thymol precipitates. *A*, From normal (Serum 12, Table I); *B*, chronic hepatitis (Serum 11, Table I); *C*, mixture of precipitates *A* and *B*.

Further evidence in support of the role of beta globulin is seen in the electrophoretic diagrams of the thymol precipitates (Fig. 2). Diagram *A* of Fig. 2 is that of the thymol precipitate from normal Serum 12 (Table I); diagram *B* is that from Serum 11 (Table I); diagram *C* represents an equal mixture of thymol precipitate from Sera 11 and 12 (Table I). From the diagrams it is apparent that the thymol precipitate consists of one major component which has a mobility of a beta globulin (Table II) and a smaller and irregularly appearing component which has a mobility of an alpha-2 globulin. It is of interest to note that the descending patterns of the thymol precipitates have the appearance of a beta anomaly. When the thymol precipitates of a normal and pathologic serum are mixed (diagram *C*, Fig. 2), the components have the same mobility and composition as the unmixed precipitates. The mobilities of the various components of serum before and after thymol treatment, of the precipitates, and of normal serum are shown in Table II.

DISCUSSION

It is obvious from the data presented that thymol reagent reacts chiefly if not exclusively with the beta globulin fraction of serum. The fact that the beta globulin levels in the thymol turbidity-positive cases are not strikingly higher than those observed with a series of normals (Table I) suggests that this fraction has an abnormal component. This is further supported by the fact that treatment of normal serum with thymol reagent results in only a small decrease in the beta globulin level (Serum 12, Table I). The precipitate, however, is indistinguishable, electrophoretically, from that obtained from pathologic serum (diagrams A and C, Fig. 2).

It is of some interest to compare the electrophoretic patterns of sera of this series of liver diseases with those from normal adults. If the average values of the pathologic sera are compared with the average values of the normal series (Table I), it will be noted that in the former group the albumin is decreased, the beta globulin is increased slightly, and the gamma globulin is strikingly increased. It should be noted also that while the gamma globulin level is increased above the normal value in all cases but Serum 9, there is no correlation between the gamma globulin increase and the thymol turbidity units. A similar lack of correlation, however, is also to be seen in the case of the beta globulins.

The known complexity of the beta globulin fraction makes any attempt at a discussion of the possible nature of the changes in this fraction in disease difficult. It is possible that there is no fundamental change in the protein components making up this fraction, but rather a change in either the kind or amount of phospholipid chemically bound with the protein. While most patients with nonobstructive liver disease do not show any consistent increase in phospholipid content of serum,¹⁰ it is possible that some alteration in the amount or type of true lipoprotein rather than total lipid is involved.

A sample of the thymol precipitate from Serum 11 was examined in the ultracentrifuge. The material had the same number and kind of components as are seen with the beta globulin fraction obtained as a by-product of fractionation of gamma globulin from normal human plasma.⁸ This normal beta globulin fraction was approximately 90 per cent homogeneous electrophoretically.⁹ Thus it would appear that on the basis of the properties in the electrophoresis

apparatus and in the ultracentrifuge, there are no physical differences to be noted between the normal and pathologic beta globulin fractions.

SUMMARY

1. Electrophoretic analyses of sera from patients with liver disease having positive thymol turbidity tests were made before and after treatment with thymol reagent. The chief change noted was a decrease of the beta globulin fraction of the supernatant after removal of the thymol precipitate.

2. The thymol precipitates obtained from sera from both normal and diseased cases were examined in the electrophoresis apparatus and both were shown to migrate with the mobility of a beta globulin. Examination in the ultracentrifuge revealed the thymol precipitate to have a composition similar to that seen with the beta globulin fractions obtained from normal human plasma.

3. The possible basis for the thymol turbidity test is briefly discussed.

A STUDY OF THE SERUM BILIVERDIN CONCENTRATION IN VARIOUS TYPES OF JAUNDICE

EYREL A. LARSON, M.D., GERALD T. EVANS, M.D., AND CECIL J. WATSON, M.D.
MINNEAPOLIS, MINN.

THE presence of a green tinge in the skin of certain patients with jaundice has long been recognized. The relation of this so-called biliverdin jaundice to the underlying disease has been discussed by various writers.^{6, 7, 10, 14}

According to recent chemical evidence,^{2, 3, 11, 18-23, 31} it is probable that biliverdin is intermediate in the catabolism of hemoglobin to bilirubin. Demonstration by Rich^{27, 28} of both biliverdin and bilirubin in the phagocytes of tissue cultures of mesothelial origin, the occurrence of biliverdin in the Kupffer cells of geese as observed by McNee,²⁵ and its presence in dog's placenta¹⁸ and hematoma fluid¹⁶ emphasize a close physiologic connection between biliverdin and hemoglobin breakdown. The "green hemoglobins" studied by Fischer,¹¹ Warburg,³¹ Lemberg,¹⁸⁻²³ Barkan,^{2, 3} and their co-workers, to which the name "verdo-hemochromogen" was given by Lemberg,²⁰ are undoubtedly biliverdin-iron-protein complexes. Assuming that biliverdin is an intermediate stage in the transition of hemoglobin to bilirubin, its reduction to the latter substance in the body normally proceeds in a manner that excludes its appearance in the serum or plasma in evident amounts.

Methods have been described for the determination of biliverdin in bile,^{1, 12} but these are not suitable for blood serum or plasma. Biliverdin does not give a diazo reaction and, thus, is not included in the quantitative van den Bergh method for bilirubin, regardless of modification. Specific color reactions for biliverdin are unknown. The purpose of the present study was to develop a method for the quantitative determination of biliverdin in serum or plasma and to apply this method in studying various patients with jaundice, especially those exhibiting greenish or outspoken green tints.

METHODS

Crystalline biliverdin was prepared by the addition of purified bilirubin* to boiling glacial acetic acid containing ferric chloride, according to Lemberg's method.¹⁷ The dry crystalline substance was weighed on a microbalance, and a 0.4 mg. per cent solution in 0.01 per cent sodium hydroxide was prepared. Employing the Evelyn photoelectric colorimeter, a transmission curve then was determined for this solution. A like curve was obtained for a similarly prepared solution of bilirubin. These curves are shown in Fig. 1. Inspection establishes the suitable wave length for measurement of biliverdin between 635 and 690 millimicrons. Between these two points bilirubin transmits well, whereas biliverdin has a relatively great absorption. Thus, the 660 μ filter was employed in the present study.

From the Department of Internal Medicine and Hospital Laboratories of the University of Minnesota Hospitals.

The use of direct regional spectrophotometry in this determination necessitates exclusion of the presence of appreciable quantities of reduced and oxy-hemoglobin, methemoglobin, methemalbumin, hematin, and sulfhemoglobin. These interfering pigments, in contrast to biliverdin, absorb more light in the region of 620 to 635 $m\mu$ than at 660; initial comparison in these two regions thereby serves to indicate their presence. Fortunately the interfering pigments are seldom encountered in carefully manipulated unhemolyzed specimens, though the presence of any appreciable quantity of any one substance casts doubt upon the results of the biliverdin determination. Furthermore, the use of nonturbid, fasting sera is obviously necessary. The reader is referred to the work of Drabkin and Austin⁸ for further orientation concerning the light absorption of the various forms of hemoglobin.

Fig. 1.—Transmission curves for solutions of crystalline bilirubin and biliverdin.

A calibration curve was determined as follows: One cubic centimeter quantities of clear, fasting normal sera, containing varying known quantities of added crystalline biliverdin in solution, were added to 8 c.c. quantities of distilled water and mixed. The resultant turbidity was then dispelled by the addition of 1 c.c. of saturated sodium chloride solution. Utilizing the Evelyn colorimeter, the 660 $m\mu$ filter, and a predetermined center setting (see next paragraph), a straight-line relationship was observed when the galvanometer readings were plotted against concentration on semilogarithmic paper (Fig. 2).

Normal sera, containing no biliverdin as evidenced by no dip in transmission between 620 and 660 $m\mu$, even when they appear to be clear, may give

galvanometer readings between 98 and 100 when a blank (containing 9 c.c. of water and 1 c.c. of saturated sodium chloride) is set at 100. Consequently, a center setting of the instrument is determined from a diluted normal serum which, after giving a reading of 98 against the theoretical blank, is then set to read 100. This precaution prevents the apparent measurement of biliverdin when actually none is present, but conversely, very small amounts, less than 0.02 mg. per cent may be missed.

The serum bilirubin was determined by the method of Malloy and Evelyn,²⁴ modified in accordance with the recommendation of Ducci and Watson.⁹

Fig. 2.—Calibration curve obtained by adding varying amounts of crystalline biliverdin to normal serum.

RESULTS

The sera of twelve nonjaundiced individuals, including both hospital patients and normal healthy persons, were examined for biliverdin. None was found in this series by the method described. Values ranging from zero to 2.2 mg per cent were obtained in the course of 105 observations on the sera of sixty-six patients with jaundice.

Significant levels of serum biliverdin were found in the following patients: twenty-seven with carcinomatous obstruction of the common bile duct (Fig. 3), five with infectious hepatitis (Fig. 4), five with cirrhosis and jaundice

		.42	4.0

*Questionable biliverdin.

(Fig. 4), and five with common bile duct stenosis (Fig. 5). Among these were fourteen individuals with a total bilirubin under 10 mg. per cent (average, 5.9 mg. per cent). On the other hand, of ten with calculous obstruction of the common duct, five had no biliverdin in the serum, although their average total bilirubin was 7.1 mg. per cent (Fig. 5).

The remaining fourteen patients (Table I) with a range of total bilirubin from 3 to 30 mg. per cent (average 7.6 mg. per cent), twelve of whom had

Fig. 3.—Serum biliverdin values in twenty-seven patients with carcinomatous obstruction of the common bile duct plotted against the total serum bilirubin (per cent biliverdin of total bilirubin represented by the radiating lines).

either a hemolytic process or bilirubinemia of the predominantly indirect type, all had zero biliverdin. The interference of methemalbumin in the method was not recognized early in the study but undoubtedly accounts for the slight galvanometer deflection in the patient marked by the asterisk (Table I), in which a definite in vivo hemolysis was known to have occurred.

Fig. 4.—Serum biliverdin values plotted against total serum bilirubin in patients with infectious hepatitis and cirrhosis.

Fig. 5.—Serum biliverdin and total bilirubin values in patients with stone, stricture, and atresia of the common bile duct.

A variation in biliverdin concentration without respect to the direction of change in total bilirubin was noted during serial observations on twelve patients (Figs. 6 and 7); of these, the three in Fig. 7 stood out as being the

only ones who had received food or intravenous feeding to raise their caloric intake above basal requirements, resulting in a weight gain in two instances. In these three biliverdinemia disappeared completely despite the absence of any marked change in the total serum bilirubin.

A green tint was observed in the skin of patients having as little as 0.3 mg. per cent in the serum.

Fig. 6.—Changes in the serum biliverdin and bilirubin concentrations in serial studies.

Fig. 7.—Disappearance of biliverdinemia without corresponding change in total serum bilirubin in patients with notably high caloric intakes.

DISCUSSION OF RESULTS

Lemberg and Wyndham²¹ demonstrated a rapid, *in vitro* transformation of biliverdin to bilirubin in the presence of liver, kidney, and brain tissue and a

slower change in the presence of other tissues. They also observed a more rapid and complete transformation by the liver tissue of well-fed animals as compared with that of starved animals; furthermore, the addition of glucose to the tissue preparations from the latter animals accelerated the change. Lemberg²² further emphasized the role of the liver in the reduction of biliverdin to bilirubin and the particularly close connection between the metabolism of bile pigment and carbohydrate in the liver.

The latter hypothesis gains possible support from the experience of Kanasaki,¹⁵ in which green bile in the duodenal drainage of a patient with cirrhosis was replaced by orange bile after administration of intravenous glucose. Furthermore, biliverdin rather than bilirubin is excreted in the bile of starving dogs¹³ and by frogs²⁶ whose livers are low in glycogen content. The oxidation-reduction possibilities which may exist in the liver and biliary duct system, both in health and disease, have been discussed by a number of investigators.^{4, 5, 22, 23, 29, 30}

In the present study the trend was for the higher values of serum biliverdin to occur in patients with the higher values for total bilirubin, though notable exceptions occurred. In agreement with the findings of Eppinger,¹⁰ the results indicate that the most pronounced biliverdin icterus and the highest values for serum biliverdin were associated with neoplastic obstruction of the common bile duct. However, biliverdinemia was a feature of other types of regurgitation jaundice as well, especially infectious hepatitis. The bulk of evidence favors a failure of change in biliverdin to bilirubin in the liver and/or other tissues. Noteworthy in this respect is the lack of biliverdinemia in the patients with hemolytic jaundice in which there was an obvious rapid transformation of blood to bile pigment. As to causes of biliverdinemia other than a failure of the liver or other organs and tissues to reduce biliverdin to bilirubin, the spontaneous oxidative formation of biliverdin from bilirubin in the gall bladder and bile ducts, with subsequent reabsorption, must be considered. In this regard, the patients with a high biliverdinemia did not show greater clinical evidence of infection than those with equal jaundice and less biliverdinemia. Furthermore, serial observations in twelve patients indicated that the serum biliverdin concentration can change markedly in one to five days without corresponding change in total bilirubin and, therefore, in the case of common duct obstruction, without change in the reabsorption possibilities from the biliary tree.

In contrast to the clinical observations of Brugsch⁶ and Horsters,¹⁴ biliverdinemia was not observed in jaundice due to hemolytic processes.

SUMMARY AND CONCLUSIONS

1. A direct spectrophotometric method for the quantitation of biliverdin in serum or plasma is described.
2. Observations on sixty-six patients with jaundice due to various causes are summarized. In general, biliverdinemia is a feature of regurgitation jaundice; it has not been observed in hemolytic (retention) jaundice. Absence of biliverdinemia speaks against a diagnosis of jaundice due to neoplastic obstruction.

3. There is suggestive evidence that biliverdinemia is abolished in jaundice when the nutritional status of the patient improves.

DIFFERENTIAL AGGLUTINATION OF HUMAN ERYTHROCYTES

EVALUATION OF TECHNIQUE

LAWRENCE E. YOUNG, M.D., RICHARD F. PLATZER, M.D.,
AND JAMES A. RAFFERTY, M.D.
ROCHESTER, N. Y.

WITH THE TECHNICAL ASSISTANCE OF
BERDINE PROCTOR AND MARY JANE IZZO, B.A.

THE differential agglutination of erythrocytes depends upon a specific reaction between the agglutinin of an antiserum and the agglutininogen of red cells. After transfusion of red cells lacking an agglutininogen present in the cells of the recipient, it is possible to agglutinate the cells of the recipient by use of an appropriate antiserum. Conversely, after transfusion of erythrocytes containing an agglutininogen not present in the cells of the recipient, but for which the recipient's serum has no specific agglutinin, the donated corpuscles can be differentially agglutinated.

Inasmuch as this procedure has many applications in investigative medicine, it was deemed worth while to study the factors affecting the accuracy of the method and to determine the most satisfactory quantitative procedure. The objectives of this paper are (1) to describe the technique currently used by this laboratory and (2) to present the practical, experimental, and statistical considerations which led to the adoption of this technique.

HISTORICAL

In 1919 Ashby¹ first studied the fate of transfused erythrocytes by giving Group O cells to recipients belonging to one of the other major groups. She found, for example, that after transfusing Group O cells to a Group A recipient, the latter's cells could be agglutinated with anti-A (Group B) serum and that the unagglutinated O cells of the donor could then be enumerated by transferring the serum-cell mixture to a counting chamber. Wiener^{2, 3} later demonstrated that differences in MN type could be utilized in a similar manner. After transfusing AN cells, for instance, to an AMN recipient, the latter's cells were agglutinated by anti-M serum and the unagglutinated AN cells of the donor could be counted as in the method of Ashby. By utilizing both ABO and MN differences, it was soon proved feasible to make observations simultaneously on the fate of cells from two or three different donors in the circulation of a single recipient.

From the Departments of Medicine and Pathology, The University of Rochester School of Medicine and Dentistry.

The studies described in this paper were carried out under a contract between the Office of Naval Research and the University of Rochester.

Received for publication, March 28, 1947.

Ashby's technique consisted of filling a leucocyte pipette with capillary blood to the .5 mark. The pipette was then filled to the 1.1 mark with a 20:1 mixture of serum and 4.4 per cent citrate solution. The mixture was expelled into a small test tube, shaken, incubated at 37° C. for forty minutes with shaking every ten minutes, and then placed in an icebox overnight. On the following day the mixture was shaken, a drop placed in a counting chamber, and the cells in 160 small squares in each of two chambers were counted. A tube containing the blood of a nontransfused individual was used as a control to test the agglutinative capacity of the serum, and the same serum was used throughout each experiment. Ashby⁴ later advised against refrigeration of serum-cell mixtures because of nonspecific agglutination caused by low temperatures.

In 1922 when Wearn and associates⁵ used Ashby's method to determine the life of transfused red cells, they noted that, of the cells which should have been specifically agglutinated, from 20,000 to 50,000 per cubic millimeter remained unagglutinated and they considered 50,000 such cells per cubic millimeter the upper limit for satisfactory sera.

In 1924 Jervell⁶ made a comprehensive study of the factors affecting the accuracy of Ashby's technique. He used saline suspensions of cells mixed with agglutinating sera of high titer and found that shaking of serum-cell mixtures for one minute was adequate and that further shaking did not alter the counts.

Landsteiner and co-workers⁷ in 1928 first employed M and N factors in a study of the longevity of type M donated cells in a recipient of type N, and Wiener and associates^{8, 9} applied M-N differences to the study of transfusion reactions and storage of blood.

Mollison and Young,^{10, 11} who applied the principle of differential agglutination to the study of various blood preservatives, drew capillary blood into a hemoglobinometer pipette, mixed it with citrate, and then mixed the cell suspension with antiserum in a flat-bottomed bottle. Anti-A, -B, -M, and -N sera were used, and two individuals enumerated the unagglutinated cells.

Dacie and Mollison¹² in 1943 further refined the technique during the course of their studies on hemolytic anemias. They added 20 c. mm. of capillary blood to 1.0 c.c. of saline, or 0.1 c.c. of venous blood to 5.0 c.c. of saline; the resulting cell suspension was mixed with an equal volume of potent anti-A or anti-B serum, allowed to stand an hour, centrifuged, shaken, and again centrifuged. Anti-M and anti-N sera were used in the same way with the exception that the serum-cell mixtures were allowed to stand two hours and were not placed in the centrifuge.

The technique of Dacie and Mollison was used with notable success by Brown, Hayward and co-workers¹³ and by Callender and associates¹⁴ in their investigations of the manner of destruction of transfused normal erythrocytes by normal and anemic recipients. This method also has been employed by Young and Lawrence^{15, 16} whose only deviation was that of preparing an initial 1:101 dilution of blood in saline instead of a 1:51 dilution as recommended by Dacie and Mollison.

Other techniques of differential agglutination have been developed and successfully used by Dekkers,¹⁷ Denstedt and co-workers,¹⁸ and Thalhimer.¹⁹ Ebert and Emerson,²⁰ who made a thorough study of the hemolytic effect of Group O blood and pooled plasma, were the first to describe the use of dried antiserum for differential agglutination, an innovation having advantages which will be enumerated subsequently. It is the technique of these authors^{20, 21} that has been followed to the greatest extent in developing the method currently adopted by this laboratory.

In 1924 Isaacs²² criticized studies employing the technique of differential agglutination of cells. He stated that reticuloocytes and nucleated red cells were nonagglutinable and were largely responsible for the error of the method. Subsequent observations in other laboratories and those reported in this paper show clearly, however, that reticuloocytes are readily agglutinated by the usual antisera.

APPLICATIONS OF THE TECHNIQUE

The applications of the technique of differential agglutination are described in detail in the publications to which references have been made and are reviewed briefly elsewhere.²³ These applications may be enumerated as follows:

1. Determination of the life span of normal red cells by transfusion to normal recipients. By this method the erythrocyte has been found to survive for periods as long as 120 days or more.¹⁴

2. Study of pathologic destruction of red corpuscles in hemolytic disorders by "cross-determination of the lifetime of erythrocytes."^{12, 16, 24, 25} Normal cells are transfused to patients with hemolytic anemia and cells from the latter are transfused to normal recipients in an effort to determine whether intra- or extracorporeal abnormalities, or both, may be present.

3. Investigation of transfusion reactions in which incompatible donated cells are rapidly destroyed by the action of regular or irregular isoagglutinins of the recipient, or in which the recipient's cells are subjected to the hemolytic effect of transfused plasma or Group O blood.^{9, 20, 26, 27}

4. Evaluation of the effects of storage, preservatives, and methods of transport of whole blood and red blood cells.^{8, 10, 11, 18}

5. Observations on the selective action of the spleen on abnormal autologous cells as contrasted with normal donated cells.^{28, 29}

THE TECHNIQUE

Five cubic centimeters of venous blood are withdrawn into a dry syringe with a minimum of stasis, and after removing the needle, the blood is expelled into a bottle containing 4 mg. of dried potassium oxalate and 6 mg. of dried ammonium oxalate.³⁰ After gentle rotation, 0.5 c.c. of the oxalated blood is transferred with a volumetric pipette to a 100 c.c. volumetric flask which is then filled to the mark with fresh normal saline. After thorough mixing, 0.2 c.c. portions of the 1:200 suspension are transferred with a serologic pipette

to each of four test tubes of approximately 7 mm. inside diameter and 6 cm. length. Tubes 1 and 2 contain only the saline suspension of cells, while tubes 3 and 4 contain 2 to 4 mg. of dried anti-M or anti-A serum.* This is the amount which can conveniently be held on the broad end of a toothpick, and no more accurate measurement than this appears to be necessary or practical. All the tubes are shaken gently and after about three minutes tubes 3 and 4 containing the serum-cell mixtures are centrifuged for one minute at 1,000 revolutions per minute. They are then shaken for fifteen seconds by rapid flicking against the table and after standing five minutes or longer at room temperature the mixtures are counted.

Fig. 1.—Diagram of technique.

After reshaking for fifteen seconds the cell suspensions and serum-cell mixtures are transferred to a bright-line counting chamber by means of large bore (0.8 to 1.2 mm.) capillary tubes which are discarded after a single filling. Each of two individuals fills one side of a chamber from each of the four tubes and counts the red cells in two sets of five squares (each square measuring 200 microns) in each side of a chamber as indicated in Fig. 1. By this procedure, 4 saline and 4 serum counts of five squares each are made by each person, thus giving a total of 8 saline and 8 serum counts. In counting fields where agglutinated cells are present, any square containing a large clump is omitted and an adjacent square is counted in its place. Both persons enumer-

*The dried antisera used in these studies were purchased from Lederle Laboratories, Pearl River, N. Y.

ate the cells simultaneously and with a minimum of delay. Counts are discarded and repeated if (1) either person suspects a break in technique or (2) the difference between the average counts for five squares is greater than 1.5 standard deviations.

The same lot of serum is used throughout each investigation, if possible, and the serum is tested at the beginning of the experiment, and periodically thereafter, for its ability to agglutinate the cells which possess the specific agglutinin. If less than 10,000 per cubic millimeter of the cells containing the agglutinin for which the antiserum is specific are left unagglutinated, no correction factor is necessary. If from 10,000 to 50,000 cells per cubic millimeter are left unagglutinated, this correction factor is subtracted from each serum count. If more than 50,000 cells per cubic millimeter fail to agglutinate, the serum is considered unsatisfactory for use in this procedure. This means that 99 per cent of the cells must be agglutinated if the suspension used contains 5 million cells per cubic millimeter.

The calculations made after completing each group of counts are most easily presented by citing an example such as that of an OMN recipient transfused with ON erythrocytes. Following such a transfusion, anti-M serum agglutinates nearly all of the recipient's cells and leaves unagglutinated all of the donated cells which are enumerated in the serum count. In this case:

- (1) Total number of red cells per cubic centimeter (that is, OMN + ON cells) = (Average of 8 saline counts of five squares each) \times 10,000
- (2) Number of ON cells per cubic millimeter = (Average of 8 serum counts \times 10,000) - the correction factor
- (3) Number of OMN cells per cubic millimeter = Total number red cells per cubic millimeter - number ON cells per cubic millimeter

If typical figures are substituted in these formulas as examples, the following results are obtained:

- (1) $425 \times 10,000 = 4,250,000$
- (2) $(170 \times 10,000) - 20,000 = 1,680,000$
- (3) $4,250,000 - 1,680,000 = 2,570,000$

It is to be noted that the average of the saline counts made by this method provides an accurate count of the total red cells per cubic millimeter when the figure is multiplied by 10,000.

If the number of unagglutinated cells in the serum-cell mixture is below 100 per set of five squares, it is advisable, because of large Poisson errors, to make a separate saline suspension containing 1, 2, or 4 c.c. of oxalated blood in 100 c.c. of normal saline and to use this suspension for mixing with anti-serum. Counts obtained are then divided by 2, 4, or 8, respectively, in the final calculations.

When liquid antiserum is used instead of the dried preparation, 1.0 c.c. of oxalated blood is ordinarily diluted to 100 c.c. with saline and 0.2 c.c. of the 1:100 suspension is placed in each of four tubes as is done when dried serum is used. To tubes 1 and 2 is added 0.2 c.c. of saline and to tubes 3

and 4 is added 0.2 c.c. of antiserum. The remainder of the procedure is the same with liquid sera, with the exception that it may be necessary to shake the serum-cell mixtures more gently than when dried antisera are used. The optimum amount of shaking may vary from serum to serum, either wet or dry, and it is therefore necessary that this amount be determined for each lot of serum at the beginning of an experiment.

FACTORS AFFECTING THE ACCURACY OF THE TECHNIQUE

Selection of Donor-Recipient Combination Prior to Transfusion.—Since anti-A, -B, and -M sera give quantitative results, as will be shown in the discussion of antisera, it is possible to use differential agglutination in the combinations given in Table I. Inasmuch as the cells of all individuals in the population contain either the M or the N factor, or both, it is possible to carry out this procedure with all recipients. When Group O blood is given to A, B, or AB recipients, it is advisable to use only the red cells²⁰ or to add A and B substances to whole blood. The deliberate transfusion of Rh-positive blood into Rh-negative recipients for the purpose of studying differential agglutination is potentially dangerous and unjustifiable, particularly if there are to be repeated transfusions or if pregnancy is anticipated in the case of the Rh-negative female recipient. Likewise, the repeated transfusion of A₁ blood to an A₂ recipient or vice versa may be potentially dangerous, especially if the recipient is suffering from a hemolytic disorder.²¹

TABLE I. MIXTURES OF DONOR'S AND RECIPIENT'S BLOOD MOST SATISFACTORILY USED IN DIFFERENTIAL AGGLUTINATION

RECIPIENT'S GROUP	DONOR'S GROUP	SERUM USED TO DIFFERENTIATE	UNAGGLUTINATED CELLS
A	O	Anti-A	O
B	O	Anti-B	O
AB	O	Anti-A, Anti-B, or both	O
	A	Anti-B	A
	B	Anti-A	B
N	M	Anti-M	N
	MN	Anti-M	N
M	N	Anti-M	N
MN	N	Anti-M	N

Sampling of Recipient's Blood.—Best results have been obtained with 5 c.c. samples of venous blood drawn into dry, sterile syringes without stasis and transferred to bottles containing dry oxalate mixture. Capillary blood may be used if venous blood is not readily obtainable, but it is to be kept in mind that some accuracy is sacrificed in taking small samples.* Capillary blood is most easily drawn with a hemoglobinometer pipette from which a 0.02 c.c. sample is transferred to a tube containing 4.0 c.c. of saline, thus giving a

*It should be emphasized that the hematocrits of venous and capillary blood may differ significantly and that both may differ widely from the "whole body" hematocrit. The results of differential agglutination tests made after transfusion should be interpreted with these hematocrit variations in mind.

1:200 dilution of cells as in the method employing venous blood. Capillary samples are best taken and diluted in duplicate in order to reduce the error inherent in the use of small volumes.

Preparation of the Saline Suspension.—The 0.5 c.c. volumetric pipettes, which are used routinely in transferring venous blood samples to the 100 c.c. flasks, have an error of not more than 0.1 per cent, while ± 16 c.c. is the tolerance for error of the 100 c.c. volumetric flasks. Multiple dilutions with the accompanying increase in error are avoided by this method. It is important, if accurate results are to be obtained, that saline suspensions be of such density as to provide counts of between 400 and 500 and never less than 200 cells per five squares. Stronger suspensions should be made if the counts do not fall within this range. As previously stated, more concentrated suspensions of cells in saline should be prepared to mix with antiserum if the counts of unagglutinable cells fall below 100 per five squares. The coefficient of variation for a count of 100 is 9 per cent and is larger for counts smaller than 100.

Differential counts are sometimes made on the nonhemolyzed cells remaining in the bottom of each tube used in testing the osmotic or mechanical fragility of mixtures of two types of cells present in peripheral or splenic blood.^{28, 29} When this is done, the cells are resuspended in normal saline until the density of the suspension matches that of a standard tube of the same size containing a 1:200 dilution of whole blood having a red cell count of from 4.0 to 5.0 million. Two-tenths cubic centimeter portions of the resuspended cells are then transferred to four small tubes, and the remainder of the procedure is carried out in the usual way. The proportions of the two types of cells can be determined from counts made on such preparations.

The Antiserum.—

The Antisera to Be Used: In light of the present knowledge of the agglutinogens of human erythrocytes, it is theoretically possible to use eleven different antisera for this purpose. These antisera are anti-A, -B, -A₁ (absorbed B), -M, -N, -P, -Rh₀, -Rh', anti-Rh'', -Hr', and -Hr''. In the final analysis the accuracy of the procedure depends to a great extent on the quality of antiserum used. Of the sera available in our laboratory only anti-M, -A, and -B have been satisfactory.

Dried serum has the advantages of relatively uniform potency, stability, and economy. The fact that dried antiserum, in the amounts used, does not dilute the saline cell suspensions was proven by comparing the counts of saline suspensions of AN cells before and after adding dried anti-M serum in the usual proportions. The difference between the counts was only 2.8 per cent, revealing no apparent dilution or nonspecific agglutination. This experiment was repeated using dried anti-N serum and AM cells and the difference in counts was less than 4 per cent.

The Proportion of Antiserum and Cell Suspension: The amount of dried serum, which causes nearly complete specific agglutination and no nonspecific agglutination, has been determined by our experiments to be from 2 to 4 mg. per 0.2 c.c. of cell suspension. Amounts of from 4 to 8 mg. in 0.1 c.c. of cell suspension caused nonspecific agglutination in the case of anti-N serum. For

practical purposes the amount which can be held on the broad end of a toothpick (2 to 4 mg.) gives satisfactory results.

Correction Factor for Nonagglutinable Cells: The problem of correction factors based upon counts of unagglutinated cells made prior to transfusion has been extensively dealt with in the literature.^{5, 10, 22} To be satisfactory for use in this procedure the serum should leave unagglutinated not more than 50,000 cells per cubic millimeter, or more than 1 per cent of cells containing the specific agglutinin. Frequent retesting of the antisera, particularly liquid antisera, to check the correction factor is advised. As shown in Table II, the nonagglutinable cells amounted to only 0.2 per cent with dried anti-M serum and 0.5 per cent with dried anti-A serum currently in use in this laboratory.

The theory that nonagglutinable cells are reticulocytes or nucleated cells is untenable in view of the work of Callender and associates¹⁴ and the following observations made in this laboratory:

1. The freshly drawn erythrocytes which were left unagglutinated after mixture with anti-A, -B, and -M sera were stained with brilliant cresyl blue and no reticulocytes or morphologically abnormal cells were found.

2. Dried anti-M serum was added to a suspension of MN cells from a patient with chronic hemolytic anemia. Although 51 per cent of the cells were reticulocytes, only 2 per cent were left unagglutinated, which means that most of the reticulocytes were agglutinated as were the mature cells. At the beginning of a previous experiment,¹⁵ when 73 per cent of the erythrocytes from this patient contained reticulum, only 0.5 per cent were left unagglutinated by liquid anti-M serum.

Potency of Antiserum: In order to test the effectiveness of various antisera in differential agglutination, suspensions of washed, fresh A₁MRh+, BNRh+, OMRh-, and A₂MRh+ cells were prepared in saline. Counts were made on each suspension, 1.0 c.c. portions of each suspension were combined to make a mixture of the four types of cells, and this mixture was then counted. To portions of the mixed cell suspension, anti-A, -B, -A₁, -M, -N, and -Rh₀ sera were added by the technique described. In order to determine the nonagglutinable cell count, each of these antisera was tested with that suspension of cells containing the agglutinin for which it was specific; for example, the anti-B serum was tested with the BNRh+ cells. Four counts of five squares each were made by each of four individuals on each saline suspension and serum-cell mixture.

This experiment was designed to test the accuracy of differential agglutination with the antisera which were available in our laboratory on a given date. Although the results of this experiment which are shown in Table II apply only to the sera tested, similar observations may be carried out to compare the potency of other sera and to determine the accuracy of the procedure. It is apparent that only the anti-M and anti-A sera tested were sufficiently potent to agglutinate 99 per cent of the cells containing the specific agglutinin. A comparison of expected per cent nonagglutinated cells and the actual per cent of nonagglutinated cells in the mixture of cells is shown in Table II. The

TABLE II. RESULTS OF DIFFERENTIAL AGGLUTINATION OF ARTIFICIAL MIXTURE OF ERYTHROCYTES WITH ANTISERUM

ANTISERA	AVERAGE OF 4 COUNTS BY EACH OF 4 PERSONS	ACTUAL PER CENT NOT AGGLUTINATED*	EXPECTED PER CENT NOT AGGLUTINATED	PER CENT DIFFERENCE + OR -	PER CENT NONAGGLU- TINABLE†

‡Not agglutinated.

§Agglutinated.

anti-A₁ and anti-N sera yielded results grossly different from those expected. These results illustrate the consequence of using antisera of low potency and specificity. The dried anti-B serum used in this experiment left 4.71 per cent of B cells unagglutinated, whereas previous lots of liquid anti-B serum obtained from donors immunized with A and B substances were considerably more potent. Additional lots of dried anti-B serum have not yet been tested in this laboratory.

Minimum requirements for blood grouping and typing sera have recently been set forth by the National Institute of Health.³²

The Reaction of Specific Agglutinin and Agglutinogen.—

Time: The time required for maximal agglutination varies widely depending upon the avidity of the serum and whether or not the serum-cell mixture is centrifuged. In our experience and that of other recent investigators,²¹ three minutes before centrifuging and five minutes afterward are adequate.

Centrifugation of Serum-Cell Mixtures: It is well known that hemagglutination is greatly accelerated by centrifugation of serum-cell mixtures. Dacie and Mollison¹² recommend that the mixtures containing liquid anti-A or anti-B serum be allowed to stand for at least sixty minutes before centrifugation. The experience of this laboratory indicates, however, that a period as short as three minutes is adequate for dried anti-A and anti-M sera and probably for liquid anti-A, anti-B, and anti-M sera. Ebert and Emerson²⁰ and Emerson and Shen²¹ have also found that it is necessary for mixtures containing dried anti-A or anti-B serum to stand only a few minutes before centrifugation.

Since anti-M and anti-N sera are absorbed rabbit sera, nonspecific reactions between these sera and human cells may often be encountered.^{3, 19} Dacie and Mollison have cautioned against centrifugation of mixtures containing anti-M or anti-N serum because of the danger of causing nonspecific clumping of type N cells by an occasional lot of liquid anti-M serum, but this has not been true of the lots of dried anti-M serum thus far tested. Both liquid and dried anti-N sera have been noted to cause some nonspecific agglutination in our experience, particularly after centrifugation. If centrifugation is carried out for more than one minute at 1,000 to 1,500 r.p.m. there may be some false agglutination.

Temperature: In our experience and that of other workers^{2, 10} room temperature is most satisfactory. The titer, and probably the avidity of isoagglutinins is decreased at temperatures as high as 44 to 55° C. which were recommended by Jervell.⁶ Refrigeration, on the other hand, as originally used by Ashby¹ may cause nonspecific cold hemagglutination.

Shaking: The amount of shaking to which the serum-cell mixture should be subjected is a problem which must be standardized with various sera. We have found that with potent dried antisera vigorous shaking by flicking against the table for fifteen seconds is necessary and if the shaking is too gentle false agglutination may be present. Vigorous shaking may not be necessary, however, when liquid antisera are used. Saline suspensions are shaken in the same fashion as serum-cell mixtures.

Filling the Chamber.—For filling the chamber it has been found that disposable glass capillary tubes which are from 0.8 to 1.2 mm. in diameter and 12 cm. in length are convenient and give constant results. When exceptionally large clumps of agglutinated cells are present, it is advisable to avoid them in removing samples from the tubes.^{2, 12} When saline cell suspensions were transferred to counting chambers with 1.2 mm. capillary tubes, 0.2 mm. capillary tubes and the stems (0.4 mm.) of Trenner erythrocyte pipettes, the differences in counts were insignificant. In making this comparison each of two persons made four transfers by each of the three methods and counted ten (200 mm.) squares after each transfer. It was found, however, that in transferring serum-cell mixtures irregularities were apt to occur when capillary tubes smaller than 0.5 mm. in diameter were used. Trenner pipettes have not been employed for this purpose because of the time required for their cleaning.

Counting of Cells.—Simultaneous counts by two persons of the cells in each tube make it possible to detect the unavoidable errors of technique which occasionally occur. These errors are assumed to exist, even though they have not been observed, when the differences between the counts is greater than 1.5 standard deviations. The counts are then discarded and repeated with different chambers. The 1.5 standard deviation control limit is economical, permitting a loss of only about 12 per cent of "true" counts. The standard deviation of the difference between the counts (that is, the average of four sets of five squares) obtained by two persons is:

$$\sigma (A_1 - A_2) = \sqrt{0.15 (A_1^2 + A_2^2) + .2 (A_1 + A_2)}$$

where A_1 and A_2 are the counts by the two persons (See Statistical Considerations). In the range of counts dealt with, 100 to 500, 1.5σ has the range 20 to 80.

In order to determine the better method a statistical test was done comparing: (1) two persons counting ten squares on each side of the chamber and (2) two persons counting twenty-five squares on only one side of the chamber. By each method 30 saline suspensions of different concentrations were counted. The coefficients of variation for the difference between the average number of cells in five squares (that is, the average counts) found by two persons were corrected for Poisson errors and were found to be (1) 8.2 per cent and (2)

13.4 per cent. Fisher-Z which tests the homogeneity of these values has a probability near 5 per cent. The discrepancy of these values is attributable to chamber error, more thoroughly characterized by Berkson²² as 4.5 per cent. Since the consistency between counts by different persons is used as a criterion of statistical control, the first method (1) was adopted because of its greater precision.

STATISTICAL CONSIDERATIONS

Formulation of the technique presented in this paper was based upon many practical and experimental considerations, some of which required statistical tests and judgments in the management of sampling errors in counts. A count obtained by this technique presumably will be compared with another one under different experimental or clinical conditions. Such comparisons of counts require statistical judgments based on the standard deviations of counts and differences between them. If σ_A is the standard deviation of count A, and σ_B is the standard deviation of count B, the standard deviation of the difference between counts A and B is:

$$\sigma_{(A-B)} = \sqrt{\sigma_A^2 + \sigma_B^2}$$

Similar manipulations of the standard deviation can be found in elementary statistical textbooks for other types of experimental comparisons. A 1.5 σ tolerance or error range includes about 88 per cent of random counts. In this laboratory differences between counts beyond the 1.5 σ range are conventionally considered nonrandom.

The general formula for the standard deviation of a count by the technique of this paper is given by:

$$\sigma_A = \sqrt{\frac{0.15}{N} \frac{A^2}{M} + \frac{.SA}{MN}}$$

where A is the count, which is the average count of M counts of five squares by each of N persons. The precision of any statistical test using σ_A can be enhanced by increasing M, N, and/or A. A convenient number of counts of five squares is 4 (M = 4) and persons is 2 (N = 2), and counts are held within the range 100 to 500. The first factor (.015) was determined from several hundred counts made under varying circumstances: different values of M, N, and A; saline and different antisera; different recipient-donor combinations, etc.; all of these conditions showed homogeneity of errors. This factor, which should be determined in each laboratory unless the technique described here is followed exactly, represents the relative variation due to random effects in apparatus and technique and limits the precision in high counts. The second error factor (.SA) due to Poisson errors²³ is important in low counts. For A = 100, σ_A = 9. Thus, counts smaller than 100 should be avoided by using cell suspensions of sufficiently low dilution.

Example: Accompanying the numerical example under Technique are the following calculations of errors:

$$(1) \text{ Saline count} = 425 \pm 37$$

$$\text{where } 37 = \sigma = \sqrt{\frac{0.15 (425)^2}{2} + \frac{(.8) (425)}{(4) (2)}}$$

$$(2) \text{ Serum count} = 168 \pm 15$$

$$\text{where } 15 = \sigma = \sqrt{\frac{.015 (168)^2}{2} + \frac{(.8) (168)}{(4) (2)}}$$

$$(3) \text{ Saline minus Serum} = 257 \pm 40$$

$$\text{where } 40 = \sigma = \sqrt{(37.)^2 + (15)^2}$$

In similar fashion the difference between (1), (2), or (3) counts for different clinical or experimental conditions can be tested for statistical significance by repeated application of the general formula, $\sigma_{(A-B)}$, previously given.

Example: One day after transfusion of ON blood to an OMN recipient, the technique was carried out using dried anti-M serum which agglutinated the recipient's but not the donor's cells. The serum count was 132 and a month later it was 103. The standard deviation for the difference between two counts, $A = 132$, $B = 103$:

$$\sigma_{(A-B)} = \sqrt{\frac{.015 (132^2 + 103^2)}{2} + \frac{.8 (132 + 103)}{(4) (2)}} \approx 15$$

SUMMARY

1. A technique of differential agglutination of human erythrocytes is presented in detail and its applications in experimental medicine are outlined.
2. The accuracy of the technique has been tested experimentally.
3. The precision of the technique has been analyzed and stated statistically.

CONCLUSIONS

1. The technique of differential agglutination gives accurate and precise quantitative results.
2. Antisera of sufficient potency, avidity, and specificity are necessary. Dried antisera (A, B, and M) have the advantages of stability and relatively uniform potency.
3. Reticulocytes are agglutinated in the same manner as mature cells and erythrocytes which fail to agglutinate are not morphologically abnormal.

FIBRINOGEN DEFICIENCY: CLINICAL FEATURES AND PROBABLE ETIOLOGIC FACTORS

LEONA B. YEAGER, M.D., PAUL S. RHOADS, M.D., AND SMITH FREEMAN, M.D.
CHICAGO, ILL.

IN EVALUATING factors which are responsible for a hemorrhagic state, fibrinogen deficiency is seldom considered. Yet, occasionally, as in the case to be described later, it may be an important factor.

Fibrinogen deficiency is rare. It may be either acquired or congenital. Quick¹ described the condition and reviewed the literature. The congenital type is characterized by its hereditary nature, by the tendency to bleed intermittently from birth, frequently oozing from the umbilical stump, and by a low or absent fibrinogen. Nine cases² have been reported with no fibrinogen and five³ with a reduced quantity.

The acquired form has been reported more frequently. Such instances usually show a transient fibrinogen deficiency that has been attributed to an interference in fibrinogen formation. In 1924 Opitz and Silberberg⁴ described a fatal case of generalized tuberculosis with hemorrhagic diathesis in a 3-year-old girl with no fibrinogen. At autopsy the liver was replaced by caseous masses and this finding was considered by the authors as evidence that the liver is the source of fibrinogen. In 1927 Knauer⁵ reported a case of possible purpura fulminans occurring in a 6-year-old girl during an attack of varicella. Fibrinogen was 0.015 Gm. per 100 c.c. of plasma. No liver damage was evident and it was suggested that the fibrinopenia was due to reticuloendothelial system damage. In 1930 Jürgens and Trautwein⁶ found less than 0.1 Gm. per cent fibrinogen in a 52-year-old man with extensive prostatic metastases in the bone marrow. The liver showed subcapsular deposits but otherwise was normal. They suggested that bone marrow has a role in the manufacture of fibrinogen. In 1935 Risak^{7, a} examined 230 patients with varied diagnoses and found eighteen with a fibrinogen level below 0.1 Gm. per cent; most of these did not show a bleeding tendency. They included patients with blood dyscrasias, infectious diseases, extensive burns, malignancies, and a miscellaneous group. Waldenstrom^{7, b} has recently described three patients with fibrinopenia, hyperglobulinemia, and a tendency to bleed excessively.

In the English literature in 1936 Dieckmann⁸ reported three cases of abruptio placentae with a fibrinogen level below 0.1 Gm. per cent and attributed this to the loss of blood. Allibone and Baar^{8, b} have described a complete absence of fibrinogen in an infant with obliteration of the bile ducts and biliary cirrhosis of the liver. The fibrinogen was restored to normal with treatment; however, progressive liver damage continued and death occurred in three months. They reviewed the literature, found fibrinogen normal in cases of severe liver damage, and concluded that a decrease in fibrinogen may or may not occur when the liver is diseased and that the site of formation in the liver

From Northwestern University Medical School and Wesley Memorial Hospital.

and bone marrow is fairly well established. Recently in 1946 Field and Dam⁹ reviewed the factors in production of fibrinogen and concluded that in the chick the fibrinogen levels are influenced by dietary regimen. Apparently an inadequate protein intake produced elevated fibrinogen levels which were attributed to a metabolic disturbance of the liver.

The fibrinogen level at which a hemorrhagic state appears is controversial. In 1931 Peters and Van Slyke¹⁰ gave the normal range for plasma fibrinogen as 0.2 to 0.4 Gm. per cent. In 1930 Jürgens and Trautwein⁶ considered 0.15 to 0.12 Gm. per cent as the critical level below which blood did not coagulate. Risak^{7, a} cited a patient with constitutional fibrinogenopenia whose son had only 0.02 Gm. per cent fibrinogen and no bleeding tendencies. In many cases the bleeding is intermittent even though the fibrinogen remains low or even absent. This inconsistency has been attributed to the existence of additional factors. Rabe and Salomon^{2, a} thought some change in vascular permeability may be necessary. Several authors^{2, b, d, e, f, h} have commented on the association of a thrombopenia and decreased fibrinogen. Allibone and Baar^{3, b} reported a case of congenital fibrinogenopenia with hemorrhagic manifestations with a value of 0.11 Gm. per cent and reviewed the theory that a deficiency in the factor of the coagulation mechanism may be compensated by the remaining factors. Henderson and associates^{2, b} concluded that the threshold is about 0.06 Gm. per cent.

Because the number of cases so far reported is small, a recent case encountered by us is described in detail.

CASE HISTORY

O. W.,* a 51-year-old farmer's wife, was first admitted to Wesley Memorial Hospital on Aug. 8, 1944, with complaints of diarrhea and generalized weakness both of several months duration. No evidence of a hemorrhagic tendency was present at that time, and the diagnosis was multiple dietary deficiency resembling sprue. The patient was discharged on a high caloric, high protein, high vitamin diet plus supplemental vitamins. On this therapy the diarrhea subsided in about a month and she felt greatly improved, so much so that in May, 1945, nine months after the first admission, she stopped the specific diet and the vitamin supplements. However, the food intake remained abundant and varied. Late in June, 1945, the diarrhea recurred and the weight dropped from 116 to 100 pounds. In August, ten days prior to the second entry, large black and blue areas appeared on the skin. A few days later the patient's knees became painful and discolored. Two small skin abrasions oozed constantly. On the evening before admission she injured her gum with a pin, producing bleeding which continued until about thirty-six hours after entry.

At the time of admission the patient was emaciated. Ecchymotic areas covered all extremities and were numerous about the head. Abrasions on the arm were oozing slightly. The gum at the site of the injury was bleeding freely. The knees were swollen and tender. The skin of the hands, legs, and feet was unusually firm and thick. The blood pressure was 118/80. No abnormalities of the heart, lungs, and abdomen were noted on physical examination. Throughout the next two days bleeding into the tissues, from the gum and urinary tract, became so severe that termination of the hemorrhagic state was urgently needed.

Factors involved in the coagulation mechanism† were considered. As noted in Table I, the coagulation time was seventy minutes. Since calcium is almost invariably present in sufficient concentration to promote thrombin formation when the other factors are present, a possible calcium deficiency seemed unlikely as the cause. A low ascorbic acid level could

*Patient seen through the courtesy of Dr. Edgar C. Cook of Mendota, Ill.

†Prothrombin plus calcium plus thromboplastin equals thrombin; fibrinogen plus thrombin equals fibrin.

have accounted for increased capillary fragility but not for a prolonged coagulation time. The platelets were only slightly reduced in number (although they may have been functionally abnormal). Consequently, at first the defect was thought to be a decreased prothrombin concentration. Ten milligrams of vitamin K were administered intravenously at eight-hour intervals. A blood transfusion was given three hours after the first dose of vitamin K. The transfusion was followed by immediate cessation of bleeding. It is impossible to state the degree to which the vitamin K, on one hand, and the blood transfusion, on the other, contributed to the termination of bleeding.

This patient has returned for observation on two occasions. There has been no further bleeding, the weight remained unchanged, but she still has irregular periods of diarrhea. Firmness and thickness of the skin of the hands and forearms have persisted.

The significant laboratory findings are tabulated in Tables I to IV. A fibrinogen level of 0.04 Gm. per cent was reported; this value is well below the critical level indicated by most authors. Consequently, it seemed probable that fibrinogen deficiency was an important factor in the bleeding tendency of this patient. During the next bleeding episode hematuria was noted. Small amounts of free hydrochloric acid were present in the gastric contents on each admission. Stool analysis and proctoscopy showed no abnormalities. The total fat content of dried feces was 22 per cent. The bone marrow showed no significant change; erythropoiesis was normoblastic.

A deficiency in both fibrinogen and prothrombin probably existed simultaneously in this patient. Estimation of either substance depends on the presence of the other essentials of the clotting mechanism. Spontaneous clot formation did occur in the calcified plasma used for fibrinogen determination, and sufficient repetition of analyses by two different methods in separate laboratories verified the exceedingly low level of fibrinogen in the blood. A comparison of the results obtained by the addition of thrombin and by allowing spontaneous coagulation to occur after recalcification of the plasma indicate that a slight difference is obtained by the two methods on either fibrinopenic or normal blood. Spontaneous coagulation was delayed for hours in the most fibrinopenic blood, and the clot formed at the lowest fibrinogen levels reported did not possess the physical properties ordinarily observed in freshly coagulated fibrin. In our experience the most satisfactory method of fibrin estimation is the direct determination of nitrogen in the coagulum after it has been collected and washed. The addition of calcium to plasma results in a somewhat higher value for fibrin as compared to that obtained when thrombin alone is added. This difference, although representing only 0.02 to 0.04 Gm. per cent fibrin, was quite consistently obtained on different samples of blood. Since the determination of prothrombin assumes a normal fibrinogen concentration, prothrombin estimation here would be in error. In only a few of the previous cases of fibrinopenia reported by other authors has prothrombin been considered. Allibone and Bnar^{3, 6} reported no clot in their prothrombin estimations and discussed the relationship between prothrombin and other coagulation factors. They also pointed out that the routine

*Blood transfusions were given August 19 and 24.

estimation of prothrombin assumes a normal fibrinogen. Quick¹ has stated that the bleeding in acute yellow atrophy frequently attributed to low fibrinogen is very likely due to severe hypoprothrombinemia.

Further studies were made in an effort to determine the cause of the fibrinogen and prothrombin deficiencies. Liver function was only slightly impaired as judged by the tests employed (Table II). The changes in liver function which were observed are such as one might expect to find in chronic impairment of intestinal absorption. The chronic diarrhea, gross evidence of malnutrition, flat oral glucose tolerance curve (as compared to the normal intravenous curve, Fig. 1), and low plasma vitamin A and carotene levels are all evidence of impaired gastrointestinal absorption. The moderate macrocytic anemia (Table III) and x-ray findings of dilated loops of intestine (Fig. 2) are other manifestations compatible with the diagnosis of a nutritional deficiency which would necessarily be due to impaired absorption since the patient had been on an adequate diet.

The change in intestinal absorption may have been due to a "generalized scleroderma" involving the intestine as well as the skin. However, a skin biopsy showed no abnormality other than edema. The patient's physician recently reported that the skin of the lower legs and feet has become markedly thicker during the months after she left the hospital.

Sprue was considered as a diagnosis. However, at no time did the patient complain of glossitis, and free acid was always found in the gastric contents. Nevertheless, the low plasma vitamin A and carotene levels and the presence of macrocytosis suggest sprue.

Intestinal absorption may have been affected by the pancreatic insufficiency as indicated by the poor amylase output to intravenous secretin (Table IV). The lack of therapeutic response to oral pancreatin, however, argues against pancreatic function as other than a contributory factor to the picture. The findings of fibrinogenopenia in the absence of marked

Fig 2—Persistence of barium in the small bowel and duodenum five hours after ingestion

hepatic insufficiency coupled with impaired intestinal absorption suggests that there may be some nutritional factor that is essential for the formation of fibrinogen by the body.

Treatment has consisted of supplemental and replacement measures. No further bleeding has been reported.

SUMMARY

A review of the literature reveals a paucity of reports in which fibrinogenopenia was proved to be an important factor in the production of a severe hemorrhagic state. It is for this reason that this instance is reported in detail. Whether the low fibrinogen level was due to the inability of the liver to synthesize this protein or to impaired absorption of its precursors from the gastrointestinal tract is not known. The evidence points to the latter cause. The cause of poor absorption in this case may be sclerosis of the intestinal wall similar to the changes recognized as scleroderma in the skin.

BIOCHEMICAL STUDIES DURING MALARIAL AND ARTIFICIAL FEVERS

LIEUTENANT COLONEL EDWARD A. GALL, MEDICAL CORPS, AND
MAJOR ARTHUR STEINBERG, SANITARY CORPS
ARMY OF THE UNITED STATES

THERE have been numerous inquiries into the metabolic alterations produced by fever.¹⁻¹⁰ Recent communications, however, reveal a diversity of opinion^{9, 11, 12} and a surprising paucity of observations made during the actual course of a febrile episode. Despite the current universal interest in malaria and the number of investigations directed at this disease, there are few precise data available regarding variations produced in the chemical constituents of the blood.

We were accidentally led into the study of this subject as the result of an observation on a patient who developed tetany during the course of an attack of recurrent malaria. There was present in this case neither hypocalcemia nor alkalosis but instead a profound degree of hypophosphatemia (serum inorganic phosphorus, 0.9 mg. per cent). Since this depletion of phosphorus was found to be transitory, the serum phosphorus having returned to 3.2 mg. per cent within twenty-four hours, it was thought that investigation of other patients with malaria might reveal similar findings. Accordingly, serum phosphorus estimations were made in eighteen additional cases during or within two hours after a chill. None of these showed evidence of tetany. Among these, fourteen patients exhibited serum phosphorus levels between 1.5 and 3.0 mg. per cent. In the remaining four the phosphorus level was normal. It was noted, however, that in those instances in which the serum phosphorus had been normal or at the low borderline level (3.0 mg. per cent) blood samples had been procured rather early in the chill.

Although hypophosphatemia had been described previously in association with the malarial paroxysm,⁹ it appeared that no accurate relationship had been established for its time of occurrence or duration. Moreover, there was no conformance in opinions¹¹⁻¹³ regarding the changes effected in other blood constituents. It was decided, therefore, to carry out a study under controlled circumstances and further to determine if possible the existence of parallel changes in nonmalarial fever.

MATERIALS AND METHODS

The study was carried out on three groups of patients as follows:

Group A.—Serum phosphorus levels were determined at serial intervals during sixteen febrile paroxysms in twelve patients with *Plasmodium vivax* malaria. The time of onset of the chill was noted and its relationship to the procurement of the various blood samples established (Table I).

From The Valley Forge General Hospital, Phoenixville, Pa.
Received for publication, Aug. 13, 1946.

* (a) and (b) refer to two successive paroxysms in the same patient without therapy.

Group B.—Fifteen patients with benign tertian malaria were selected with a view to excluding complicating diseases or injuries which might in some way influence observations. The studies were instituted within a relatively short period after the onset of the chill and were carried out serially until the temperature fell. Therapy or food were withheld throughout the period of observation, the patients receiving neither antimalarial nor antipyretic drugs. Water was permitted as desired. Records were kept of the temperature changes and their relationships to the time of collection. Both clotted and nonclotted samples were obtained. The anticoagulant employed in the latter consisted of sodium fluoride and mercuric chloride designed to inhibit glycolysis. Spectrophotometric analyses of the following substances were performed: serum inorganic phosphorus,^{14, 15} serum calcium,¹⁶ serum magnesium,¹⁷ serum potassium,^{18, 19} blood sugar,^{20, 21} and total blood-reducing substances.²² In addition to the afore-mentioned tests, serum protein determinations²³ also were carried out.

The results of these analyses are shown in Table II. Two additional patients (Cases XVI and XVII) were subsequently studied to determine if there was any relationship between the hypophosphatemia and the blood creatine and creatinine (Table III). Observations were carried out under the same conditions as previously outlined.

Group C.—This group consisted of ten patients subjected to artificial fever therapy. Seven of these with minor eye ailments were treated in a fever cabinet in which the temperature was raised to 104° F. (rectal) and maintained for one and one-half hours. The other three patients with paresis, were treated in a similar apparatus in which body temperature was raised to 106° F. (rectal) and maintained at this level for four hours. Fasting blood samples were obtained before the patients entered the fever cabinet and temperatures were recorded continuously by means of a thermocouple thermometer. Blood samples were obtained at intervals during the rise and fall of temperature as in Group B. The seven patients with eye disorders received only a liter of water per os during the course of the treatment and no preliminary medication. They were in a fasting state. The three patients with paresis also were in a fasting state, but they were given 200 mg. of ascorbic acid by mouth before entering the cabinet and while febrile were permitted a liter of 2 per cent saline solution.* The results in this group are summarized in Table IV.

*This was the routine at the Norristown State Hospital.

*Interval following the onset of the chill.

†Total reducing substance in the blood other than glucose; results expressed in terms of milligrams per cent of glucose.

RESULTS

Group A.—In fifteen of the sixteen paroxysms studied in this group the serum phosphorus level fell below the limit of normal (3.0 mg. per cent). The average minimum level attained was 1.9 mg. per cent with a range from 1.0 to 2.9 mg. per cent. The reduction in serum phosphorus was found to be progressive and minimum levels were not reached until some time after the inception of the rigor (Table I).

Group B.—As shown in Tables II and III, hypophosphatemia occurred in all seventeen of these patients. The average minimum level reached was 1.6 mg. per cent with a range from 0.8 to 2.7 mg. per cent. Among fourteen cases in which phosphorus levels were analyzed very early in the chill before a significant fall had occurred, the total diminution in this mineral averaged 51 per cent of the original level (range 19 to 71 per cent).

As surmised, it was found that the development of hypophosphatemia was progressive, commencing at the time of the temperature rise with the minimum level occurring after about three or four hours. Here, however, the range was wide (two to twelve hours). If the fever and serum phosphorus levels were plotted graphically (Figs. 1A and 1B), however, it was apparent that there was an inverse relationship between the two, the latter attaining its lowest level at about the time of the fever peak. Thereafter, however, the hypophosphatemia disappeared fairly rapidly despite a continued elevation or even a secondary rise in temperature. Normal blood levels were restored before the fever had wholly subsided.

Of the other blood constituents studied only glucose exhibited a consistent relationship to the changes previously noted. Since the metabolic insult of the parasitemia preceded the inception of rigor, none of the patients could be considered to be in a basal state. It was not possible, therefore, to establish a basal take-off point in this group. Nevertheless, all of the patients exhibited an elevation of blood glucose as the febrile episode proceeded. There was an obvious tendency for the glucose level to rise parallel with the fever, but this rise continued for a number of hours after the pyrexia had arrived at its peak and had begun to subside (Figs. 1A and 1B). The maximum blood sugar levels attained averaged 184 mg. per cent with a range of 138 to 250 mg. per cent. Seven cases showed values exceeding the average. From twelve of these patients urine samples were procured during and after the paroxysm, and despite the fact that in seven of them the usual renal threshold level of 180 mg. per cent was exceeded no glycosuria was detected.

In ten of the cases fractionation of blood-reducing substance was carried out. Some variation of the nonglucose fraction occurred but was inadequate in amount to account for the rise in total reducing substance. It was apparent, therefore, that the blood sugar rise observed was almost wholly the result of increase in glucose.

Despite the very significant variation in the concentration of serum phosphorus, the calcium levels remained relatively unchanged throughout the paroxysm. At times mild hypocalcemia was noted in the earlier cases sub-

jected to preliminary studies, but in none of the rigidly selected individuals was this noted. The variation in values from the inception to the termination of the episodes was a fraction of a milligram.

Serum potassium evaluations were carried out in eleven instances. Although variation did appear the values generally remained within the limits of normal (18 to 22 mg. per cent). In two cases a potassium rise to 30 and 32 mg. per cent, respectively, occurred during the period of temperature fall, but this phenomenon was not observed in the remaining nine patients.

The value of serum magnesium was determined serially in eleven patients. As with the serum potassium, such variations as were observed were usually confined within the limits of normal (1 to 3 mg. per cent). In some instances normal values were exceeded but there was no consistent relationship to the fever or other metabolites.

In ten cases total protein estimations were made. In two of these patients the protein remained unchanged. In the remaining eight an average fall of 0.8 Gm. occurred during the paroxysm (0.4 to 1.5 Gm.). In most instances a rising trend or a return to pre-existing values had appeared at the termination of the study.

In two cases blood creatine and creatinine determinations were performed. With the latter the greatest change was 0.3 mg. per cent, while with the former there was a reduction of 1 mg. at some time during the temperature rise. This alteration of about 17 per cent was transitory and values of blood creatine remained within the limits of normal (Table III).

Group C.—The chemical studies carried out in this group were identical with those in Group B. The results, likewise, were somewhat similar. Among these patients the serum phosphorus levels exhibited a progressive fall as the fever curve rose (Figs. 2A and 2B), although the degree of change was not quite as great. The minimum phosphorus levels ranged from 0.7 to 3.3 mg. per cent, the average being 2.3 mg. per cent. The average fall from the pretreatment level was 41 per cent and the range from 9 to 67 per cent. It appeared that the minimal level was reached somewhat more rapidly than in those cases with malarial pyrexia (Figs. 2A and 2B), the average time being two or three hours after the induction of fever. However, the return to within normal phosphorus limits was more rapid than in the patients with malarial fever. Despite the greater rapidity of phosphorus fall in this group, the rate of temperature rise was greater so that minimum phosphorus levels occurred with a lag of one or two hours after the temperature had reached its peak.

Although these patients were all in a fasting state at the onset of the fever therapy, many showed an elevated blood sugar in the initial pretreatment sample. This may have been on a psychomotor basis as many of the patients manifested apprehension on entering the fever cabinet. One patient with a fasting blood sugar level of 175 mg. per cent showed a subsequent rise to 294 mg. per cent when the body temperature was elevated. Later investigation revealed that this patient suffered from a previously unsuspected diabetes mellitus. Of the remaining nine patients all but one showed a hyperglycemia similar to that observed with malarial fever. the rise in blood sugar roughly approximating

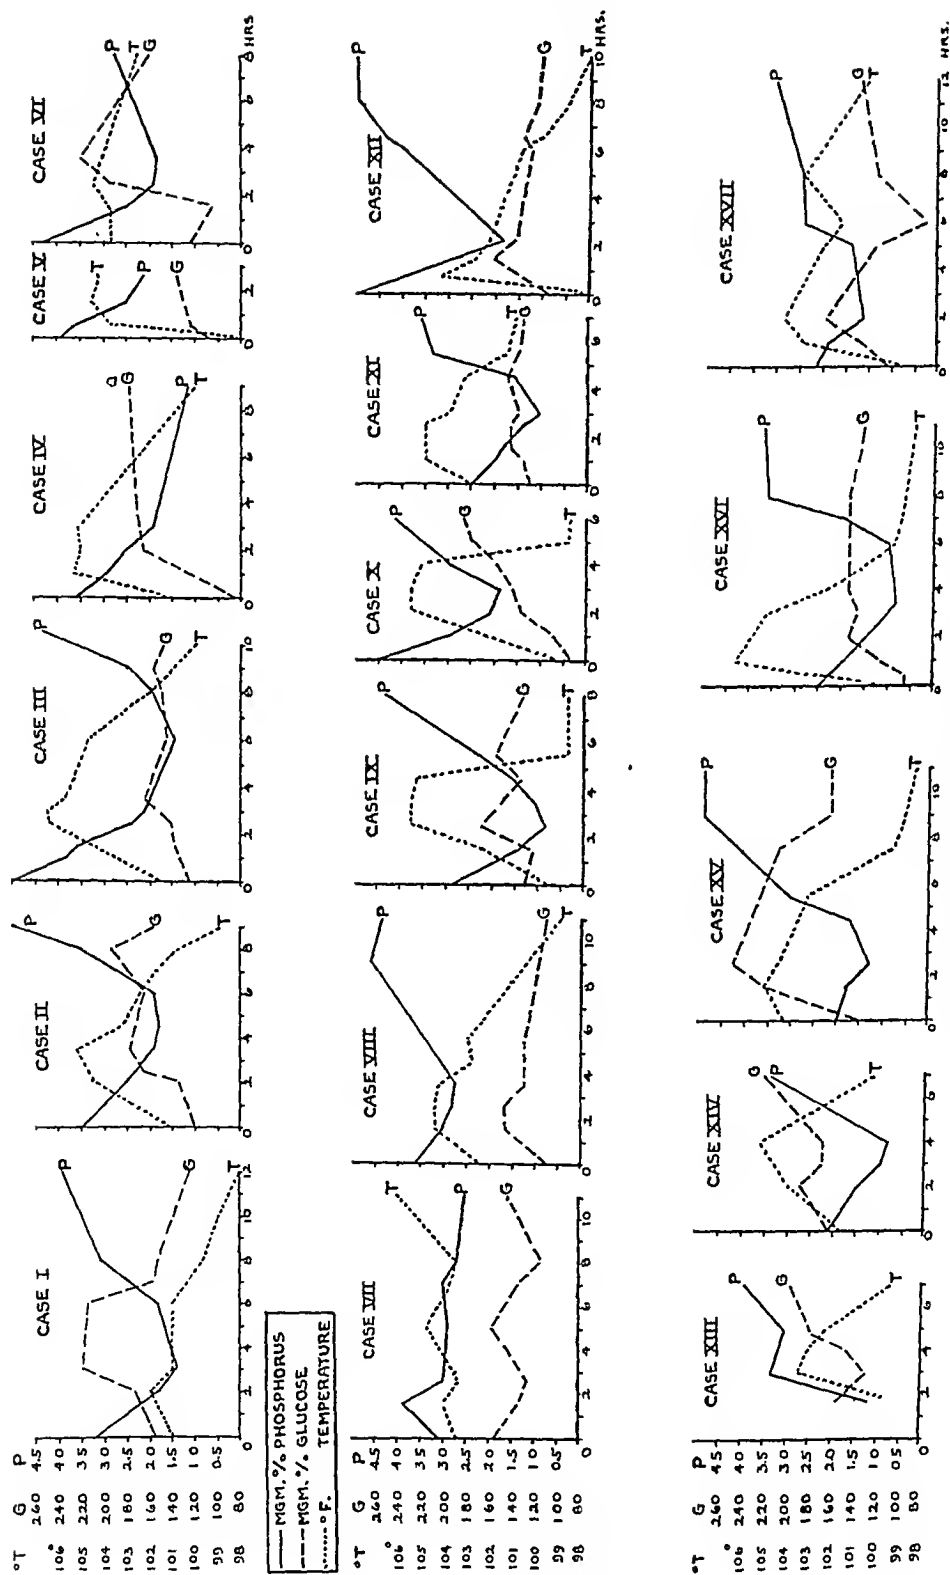

Fig. 14.—Glucose and phosphorus curves in malina.

Pls. 2B.—Mean temperature and sugar and phosphorus curves during artificially induced fever (ten cases).

the slope of the fever curve. As in the malarial group, the rise continued and the elevation persisted for a considerable period after the temperature had returned to normal.

Exclusive of the patient with diabetes (Case IV) and the patient showing no change in blood sugar (Case III), the range of maximum levels attained was 134 to 205 mg. per cent and the average was 165 mg. per cent. Four individuals from whom urine samples were obtained exhibited no glycosuria. In two of these the blood sugar level had exceeded 180 mg. per cent.

The blood from five of these patients was analyzed for nonglucose-reducing substance and, as noted previously, such variation as occurred was inadequate to account for the rise in total reducing substance. The latter therefore consisted in the main of glucose.

Alterations in serum calcium and serum magnesium were of the order previously noted in the malarial studies. The amount and kind of variation was such as to preclude importance in the metabolic processes involved. Although one patient with paresis (Case X) showed a persistent elevation of serum potassium throughout the entire study, the fluctuation in the amount of this element in the other cases was considered insignificant. The total serum protein estimations, likewise, were of little moment. In one case there was no change, in four cases an increase of 0.4 to 0.6 Gm. per cent was noted, and in two cases there was a fall of 0.4 to 0.6 Gm. per cent.

DISCUSSION

A reduction in serum inorganic phosphorus was observed initially in a group of patients with malaria. The phenomenon subsequently was shown to begin toward the end of a chill when the rise in temperature was initiated and to decline to the minimum point when the fever had attained its peak. Thereafter, the phosphorus values returned rapidly to normal limits often without the reciprocal relationship to the temperature curve originally shown. The occurrence of hypophosphatemia in association with the malarial paroxysm had been noted earlier by Payne.⁹ A similar reduction in phosphorus observed by us in a series of patients receiving artificial fever therapy paralleled those recorded previously by other investigators.^{4, 5, 10, 24, 50}

In seeking an explanation for the hypophosphatemia, blood glucose determinations were made at comparable periods. From these studies it became apparent that the fall in serum phosphorus was attended by a rise in glucose in a manner which suggested an inverse relationship between the two. It appeared on the basis of chronological observations that the blood sugar rise occurred fairly promptly in the episode, often manifested in the initial samples procured. Return to normal values was prolonged as compared to the serum phosphorus. In many instances initial sugar values had not been re-established when the temperature reached normal. Similar observations were made during the induced febrile state. In many instances a secondary rise in temperature was attended by a further elevation in the blood sugar. However, there was no concomitant secondary reduction in serum phosphorus, the latter continuing

to approach the original normal levels without deviation. We have no explanation to offer for this paradox.

It was thought that the hyperglycemia thus produced resulted from an acceleration of metabolism^{8, 25, 26} and the simultaneously increased muscular tonus.⁹ It was suspected that the hypophosphatemia was linked with increased glucose utilization, a possibility further sustained by the reduction of serum phosphorus observed following the ingestion of glucose and/or the administration of insulin.²⁷⁻³¹

It was postulated that the period characterized by the hypophosphatemia was associated with the process of phosphorylation. Glycogenolysis and glycogenesis occurring in the course of the febrile paroxysm probably were accompanied by the formation of hexosephosphate and the deposition of the latter in the blood and tissues.³² The transient linkage of phosphorus with the carbohydrate component presumably resulted in hypophosphatemia. At the conclusion of the episode, the dissociation of hexosephosphate permitted the mobilization of phosphorus, the replenishing of inorganic phosphorus, and the concomitant rise of serum phosphorus to its prefebrile level. The hexose, it would seem, was reconverted thereafter to glycogen and deposited in the tissues or was decomposed further and excreted.

Some substantiation of this thesis is found in the report of Cori and Cori³³ who noted an increased amount of hexosephosphate in muscle during muscular activity and a disappearance of this compound when activity ceased. Of parallel interest was the recorded fall of blood sugar in diabetics following the parenteral administration of sodium phosphate.³⁴

On the other hand, Payne⁹ attributed the fall in serum phosphorus during induced malarial episodes primarily to the formation of phosphocreatine. This report was encountered after much of the present study was completed, but we were able to carry out similar estimations of creatine and creatinine values in two cases during spontaneous malarial chills (Table III). Blood samples were collected in these cases at frequent intervals after the onset of the chills, throughout the febrile course, and until the patients had become afebrile. We were unable to confirm Payne's observations of significant elevations in blood creatine at the time of the temperature rise. It is interesting that he had been unable to demonstrate any hyperglycemia during or following the paroxysm.

Although such urine phosphorus examinations as were carried out in our studies were crude, there is ample evidence in the literature attesting to the fact that loss of phosphorus does not occur through this medium during the febrile paroxysm.^{4, 5, 9} Bischoff and associates^{4, 5} attributed the hypophosphatemia and concomitant hyperglycemia encountered in experimental hyperthermia to the conversion of inorganic phosphorus to the organic state. Daly and Knudson,²⁴ however, were disinclined to accept this explanation since they noted diminution of both organic and inorganic phosphorus.

The hyperglycemia in artificial fever was considered by Hench and Slocumb²⁵ to be due to hemoconcentration. This thesis obviously is not correct in view of the concomitant hypophosphatemia and hyperglycemia and the evi-

dence of mild hemodilution shown by the diminished total protein values (Tables II to IV). Petersen¹¹ observed a diminution of blood sugar during the period of temperature rise in malaria with an elevation after the temperature had fallen. This discrepancy remains unexplained since it occurred in not a single one of the cases we observed. Kirstein and Bromberg¹⁰ collected blood samples before induction and after subsidence of artificial fever. They studied no samples during the febrile period but recorded both increased glucose and diminished phosphorus after the hyperthermia. These authors considered the elevated sugar as evidence of increased glucose utilization by the tissues and also as basis for the serum phosphorus depletion. It seems reasonable to assume that results of a higher order of magnitude would have been obtained by Kirstein and Bromberg had they procured samples during the period of actual pyrexia.

Fenn,³⁶ reviewing the literature on potassium metabolism, remarked on the diminution of vascular tonus concomitant with a progressive loss of potassium and a rise in sodium during muscular activity. In our own studies of the serum potassium it did not appear that the level of this substance reflected the increased muscular activity during the rigor. For the most part the serum potassium varied only within normal limits. A few of the patients with malaria (Table II), as previously noted, showed an abrupt rise during the subsidence of the fever. One patient with paresis exhibited an inordinately high potassium level before fever was induced; this was not modified by the hyperpyrexia. None of these observations lend themselves to satisfactory explanation. A gradual elevation of serum potassium in malaria was reported by Zwemer and co-workers³⁷ and Stevenson,³⁸ the peak of rise being attained at the onset of the chill with a subsequent return to normal thereafter. Honaga¹³ observed an increase of potassium in the blood at the height of the fever in several pathologic states with a return to normal during convalescence. On the basis of our own observations it did not appear that conclusions regarding the role of this electrolyte in fever were warranted.

The inverse relationship of serum magnesium to calcium and phosphorus and its action on the neuromuscular system³⁹⁻⁴¹ led to investigation of its variations in the febrile state. In both the spontaneous and induced fevers such variations as appeared, exhibited no consistent pattern. Peters and Van Slyke⁴² have recognized this variability but were unable to offer an explanation for it. It is possible, as they suggested, that the methods for analysis used were sufficiently crude to permit such inconsistency. The magnesium values as we have observed them appear unrelated to the changes noted in other metabolites. For the most part their ranges were within normal limits.

Utilizing the amount of the total protein as an index of hydremia, it appeared that there was indeed some hemodilution of minor degree during the malarial paroxysm since the values of this substance fell rather uniformly at the febrile fastigium and rose again when the fever had subsided. Similar changes, however, were not noted in the patients with artificial fever. Certainly, there was no indication that the hyperglycemia noted was attributable to hemoconcentration as suggested by Simpson⁴³ and Hench and Slocumb.³⁵

Studies upon other constituents of the blood revealed only incidental information. Determinations of the nonglucose-reducing substances concomitantly with the total blood-reducing substances showed that the rise in the latter was indeed the result of glucose per se and not one of the other associated compounds (ascorbic acid, cysteine, glutathione, uric acid). There was a remarkable constancy of serum calcium values which remained almost wholly unchanged throughout the febrile episode.

Studies with the cephalin-cholesterol flocculation⁴⁴ and thymol turbidity⁴⁵ tests were carried out simultaneously with those previously recorded. As had been noted previously,⁴⁶⁻⁴⁸ the former were often positive in malaria. We obtained negative results in the artificial fever group. It is of interest to record that many of the patients with malaria showed positive flocculation and turbidity tests before and during the paroxysm. Others, however, showed a positive cephalin flocculation during the febrile period, the tests becoming negative when the temperature became normal. In these cases the thymol turbidity tests were negative throughout. The results of this phase of the study will be reported in detail subsequently in conjunction with a larger series of cases of miscellaneous nature.⁴⁹

SUMMARY

1. Preliminary studies on patients with malarial fever (eighteen cases) revealed the development of transient hypophosphatemia during the febrile paroxysm.

2. Serum inorganic phosphorus, calcium, magnesium, potassium, serum protein, blood glucose, and nonglucose-reducing substance were determined at various intervals during the febrile episodes in patients with benign tertian malaria (seventeen cases).

3. Similar studies were carried out on patients with artificial fever therapy (ten cases).

4. There was a marked fall in serum phosphorus attended by a significant rise of the blood glucose in all patients with malaria and in the majority of fever therapy cases so studied.

5. It was believed that the formation and deposition of hexosephosphate in the tissues was the basis for the hypophosphatemia.

6. Hyperglycemia appeared early in fever and was subsequently followed by diminution in inorganic serum phosphorus.

7. No significant alterations were observed in the serum calcium, potassium, magnesium, creatine, or creatinine.

8. The serum protein showed a slight fall during the malarial fever but remained unchanged in artificial fever.

The authors wish to acknowledge the assistance of the following individuals, whose stimulation and cooperation made this study possible: Brigadier General W. W. Vaughn, Lieutenant Colonel M. A. Schnitzer, Lieutenant Colonel S. D. Blackford, Major L. K. Alpert, Major R. R. Heffner, Lieutenant R. Stein, Mrs. Pauline Mauk, T/3 D. Campbell, of the Valley Forge General Hospital, and Dr. Arthur P. Noyes, Dr. Herbert Herskowitz, and Dr. Mortimer Raymon of the Norristown State Hospital.

NORMAL SEDIMENTATION RATES IN ACTIVE PULMONARY TUBERCULOSIS

A STUDY OF 1,066 CASES IN A NAVAL TUBERCULOSIS CENTER

THEODORE H. NOEHREN, M.D.

ROCHESTER, N. Y.

ERYTHROCYTE sedimentation tests long have been of value in determining the activity of tuberculous lesions. Like many diagnostic aids, however, the test has been abused and misinterpretations occasionally have caused loss of faith¹ in a worth-while procedure. Recent experience in a large naval tuberculosis center (Sampson Naval Hospital) has provided opportunity to observe the use and abuse of sedimentation rates for the diagnosis and evaluation of pulmonary tuberculosis.

Patients admitted to this center offered an unusually good clinical history of the infection. Each man in the Navy carries with him a so-called health record in which is entered full reports of any medical attention tendered him while in service. Thus, each patient brought with him a fairly complete medical history containing reports of previous medical studies, x-rays, and laboratory procedures.

In a rather alarming number it was seen that men with active lesions had been under observation at a recent date because of their pulmonary infiltration. Studies during the previous admissions resulted in the diagnosis of inactive disease with consequent "back to duty" discharge. The men often returned later, however, with more advanced lesions. A study of such records indicates the continuation of a fairly widespread belief that active tuberculosis always will be reflected by an increased sedimentation rate.²⁻⁵

On the basis of the foregoing considerations, a study was made of 1,066 patients with active pulmonary disease admitted to the Sampson Naval Hospital between January, 1945, and March, 1946. They were all essentially new patients never having been treated previously for tuberculosis except at the activity which forwarded them to the tuberculosis center. In some instances bed rest of varying degrees and duration had preceded their admission, but this did not prevent their inclusion in the study if other findings indicated currently active pulmonary tuberculosis.

The sedimentation rate of each patient was determined within the first few days after admission by the Cutler procedure.⁶ Normal limits of sedimentation in one hour by this method are 2 to 8 mm. for men and 2 to 10 mm. for women. No correction is necessary for hematocrit values.^{3, 7, 8} The Cutler method has been found to compare favorably with other sedimentation procedures.^{9, 10}

This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the United States Navy. The opinions and views set forth are those of the writer and are not to be construed as reflecting the policies of the Navy Department.

Received for publication, Dec. 20, 1946.

From the group of 1,066 cases, patients were selected in whom the diagnosis of active pulmonary tuberculosis was relatively certain. The criteria for this diagnosis were as follows: (1) an active pulmonary lesion by x-ray examination; (2) the presence of tubercle bacilli on three separate occasions in the sputum and/or gastric washings by smear and/or culture; and (3) no evidence of pleural fluid, pneumothorax, thoracoplasty, and no tuberculosis or other disease elsewhere in the body.

There were 300 cases meeting these qualifications. Of these, 61 (or 20.3 per cent) had sedimentation rates within the normal range (Table I).

TABLE I

GROUPS	NUMBER OF CASES	NUMBER OF CASES WITH NORMAL SEDIMENTATION RATE	PER CENT OF CASES WITH NORMAL SEDIMENTATION RATE
I	300	61	20.3
(a) and (b)			
II	240	126	52.5
(a) and (c)			
I and II	540	187	34.6
III	80	42	52.5
(a) and (d)			
I, II, and III	620	229	36.9

(a) Active pulmonary lesion by x-ray examination with no evidence of tuberculosis or other disease elsewhere in the body.

(b) Tubercle bacilli in the sputum and/or gastric washings by smear and/or culture on three occasions.

(c) Tubercle bacilli in the sputum and/or gastric washings by smear and/or culture on one or two occasions.

(d) No positive bacteriologic findings but definite cavitation by x-ray examination.

A second group was then selected in which all the previously mentioned criteria were fulfilled, except that a positive smear and/or culture of sputum and/or gastric washings was found on only one or two occasions. There were 240 cases meeting these qualifications, making a total, with the first group, of 540 cases. Of these, 187 (or 34.6 per cent) had sedimentation rates within the normal range.

Finally, a group of cases was added in which all these criteria were fulfilled, except that no positive bacteriologic findings were recorded. Instead, these patients had definite cavitation as determined by the roentgenologist, mostly on stereoscopic examinations. Cases in which cavitation was only suspected were not included.

The final group of 80, when added to the first two groups, made a total of 620 cases. Of all these, 229 (or 36.9 per cent) had sedimentation rates within the normal range.

The remaining 446 cases were complicated by pleural effusion, pneumothorax, questionable x-ray shadows, or lack of positive bacteriology. No unchallenged conclusions could be drawn from sedimentation rates in this group.

DISCUSSION

The incidence of normal sedimentation rates in active pulmonary tuberculosis in this series is strikingly large and might be difficult to accept if other examiners had not reported comparable results.

Thiele¹¹ has found that 25 per cent of open tuberculosis, 85 per cent of the cirrhotic type, 68.3 per cent of the cirrhotic-productive type, 42.3 per cent of the productive type, and 47 per cent of the cavernous type of tuberculosis have normal sedimentation rates. Leitner¹² reported normal values in 32.1 per cent, Pinner¹³ in 40 per cent, and Bobrowitz¹⁴ 45 per cent normal sedimentation rates in minimal active cases. Overholt and Wilson¹⁵ state categorically that "the vast majority of early lesions reflect no change in sedimentation rates."

Berg¹⁶ has reported eighteen cases, Banyai and Caldwell¹⁷ one hundred and eleven, Tillisch¹⁸ nineteen, and Breuhaus¹⁹ seven instances of normal sedimentation rates with active disease, the last in the face of advancing cavitation. Banyai and Anderson²⁰ stated that 7.35 per cent of cases with active tuberculosis had normal sedimentation rates, Sopp²¹ that 6.6 per cent of dispensary patients, and Rest²² that nearly one-quarter of demonstrable cases gave similar readings over a long period of time.

Pessar and Hurst²³ reported that 18 per cent of men and 12 per cent of women with active tuberculosis gave lower than expected values. De Cecio and Elwood⁸ found that in 224 patients admitted to the center with normal sedimentation rates, 61 per cent had active disease.

Several factors might be considered to explain the relatively high proportion of normal sedimentation rates in patients at the tuberculosis center. Many of these men were found to have roentgenologic evidence of tuberculosis on routine discharge examination and therefore were hospitalized with few or no symptoms of the disease. Also, the short previous hospitalization (average estimated at seven weeks) before admission to the Sampson Naval Hospital may have allowed the secondary inflammatory reactions to subside. Some observers believe that secondary reactions are chiefly responsible for the elevation of the sedimentation rate.

It seems logical to postulate that, as tuberculosis case-finding programs are expanded and more patients are found before the onset of secondary reactions with symptoms, normal sedimentation rates may also be found more frequently.

A study of active cases at the center according to the degree of anatomic involvement (by National Tuberculosis Association standards,²⁴ is interesting. In the first group of 300 relatively certain cases of active pulmonary disease, 20.9 per cent were classified as minimal, 55 per cent moderately advanced, and 24.1 per cent far advanced. Of the cases with normal sedimentation rates in that group, 44.4 per cent were minimal, 48.2 per cent moderately advanced, and 7.4 per cent far advanced. In this last 7.4 per cent was included one patient with advancing military disease who had a repeatedly normal sedimentation rate.

In these three classifications the anatomic involvement was roughly paralleled by the sedimentation rates, as has been found by others including Levinson²⁵ and Wrenn.²⁶ The average values of the 300 "relatively certain" cases are plotted according to their classification in Fig. 1. It is obvious, however, from the large proportion of normal sedimentation values in all three groups, that this parallel is not of accurate diagnostic value.

The laboratory procedures in this study were done at the Sampson Naval Hospital by Navy-trained technicians. The demobilization program with its resultant personnel changes was in effect during part of this study. Thus, these results must be considered an evaluation of the sedimentation rates in tuberculosis primarily as found in this hospital.

A few of the bacteriologic studies on these cases have been included from other naval laboratories. Re-evaluation of percentages, excluding studies done elsewhere, gives no essential change in the results.

Fig. 1.—Sedimentation rates of 300 "relatively certain" cases of pulmonary tuberculosis averaged according to anatomic involvement.

CONCLUSION

Tuberculosis per se does not always cause an elevated sedimentation rate, according to the conditions and procedure of this study. However, it cannot be denied that the test continues to be of distinct value in analyzing infectious processes, and tuberculosis is an infectious process. The sedimentation rate can continue to be extremely valuable on that basis, but on that basis only.

Except for the pathology and bacteriology of tuberculosis, our entire approach to the disease is indirect. The treatment is indirect and not specific. Diagnosis of the infection is also largely indirect. X-rays, after all, are only shadows which frequently can be misleading and often are misinterpreted and of value to a large extent from a comparative standpoint. We merely use them with these reservations as clearly in mind as possible.

The same can be said for the sedimentation test. It can, and continues to be, of help in tuberculosis until something specific, analogous to agglutination tests for other diseases, can be found. Until that time it must be used sagaciously, with all its limitations in mind.

It has been said⁸ of the sedimentation test that it will not make a good physician from a poor one, but it will make a good one better. In tuberculosis, the physician, not the test, must make the diagnosis and determine the status of its pathology.

SUMMARY

1. A study of sedimentation rates in 1,066 cases of active pulmonary tuberculosis is presented.

2. Normal sedimentation rates were found in 20.8, 34.6, or 36.9 per cent of active cases, depending upon the criteria used to determine activity of the disease. This is in agreement with reports from other sources.

3. The sedimentation curve varies roughly, but not uniformly, according to the degree of anatomic involvement by the disease.

4. Tuberculosis per se does not always cause an elevated sedimentation rate. The test, however, continues to be of value in this disease if used with careful regard for its limitations.

EFFECT OF 3,3' METHYLENEBIS (4 HYDROXYCOUMARIN) ON VITAMIN A DEFICIENT DUCKS

R. H. RIGDON AND NONA B. VARNADOE
LITTLE ROCK, ARK.

THE experimental observations of Wakin and associates¹ indicate that dicumarol* in large doses may have a toxic action on certain animals prior to the onset of hypoprothrombinemia. Several studies have shown that hypoprothrombinemia resulting from dicumarol requires a latent period of approximately twenty-four hours.²⁻⁴ Some dogs given very large doses of this drug become dyspneic, have convulsions, and are comatose preceding death. No hemorrhagic manifestations occurred during life nor were hemorrhages found at autopsy in these dogs.⁵ Dogs given intravenously 40 to 60 mg. of dicumarol per kilogram of body weight usually died within an hour without showing any changes in either the prothrombin or the coagulation times.¹

Richards and Cortell⁶ in 1942 observed that guinea pigs depleted of vitamin C succumb earlier to the effects of dicumarol. They said that "a connection between vitamin C level and sensitivity to dicumarol must be considered possible." Persons dying from infections may have a low vitamin A content in the liver.⁷⁻⁹ Apparently the mechanism of lowered resistance to infection in vitamin A deficiency is not well understood. Susceptibility may not be directly related to the deficiency, since some individuals show a normal amount of vitamin A in the presence of disease. Bessey and Wolback¹⁰ have called attention to the fact that "during a prolonged deficiency, the reserve (of vitamin A) is gradually depleted, normal cell functions are suspended, and pathologic change develops."

During recent studies on malaria in ducks it was observed that normal ducklings frequently died within three or four hours following the oral administration of large doses of dicumarol. There was observed also a variation in the time of death following the oral administration of dicumarol in ducks fed a vitamin A deficient ration when compared with birds fed a standard commercial ration. These experimental observations are reported at this time.

METHODS AND MATERIAL

Ducks used in these studies were white Pekins obtained when 1 day of age from a commercial hatchery. They were kept in small batteries and given food and water ad lib. The standard ration was duck Startena and duck Growena. The composition of the low vitamin A ration and the standard rations are as follows:

From the Department of Pathology, University of Arkansas School of Medicine.

Aided by a grant from the John and Mary R. Markle Foundation and Eli Lilly and Company, Indianapolis, Ind.

The dicumarol was supplied by The Wm. S. Merrell Company, Cincinnati, Ohio.

The vitamin A deficiency ration was supplied by the Ralston Purina Mills, St. Louis, Mo., through the courtesy of Dr. Homer Patrick.

Research paper No. 835, Journal Series, University of Arkansas.

Received for publication, Dec. 21, 1946.

*Dicumarol is the collective trade-mark of the Wisconsin Alumni Research Foundation and is used for 3,3' methylenebis (4 hydroxycoumarin).

LOW VITAMIN A DUCK RATION

Mineralized salt	0.25
Puriflavin (250)	1.00
Calcium carbonate	2.00
Soybean oil meal	18.00
Wheat germ	5.00
Fish meal (60%)	6.00
Meat scraps	4.00
Brewers' yeast	5.00
Ground wheat	19.65
White corn	29.00
Ground oats	5.00
Molasses	5.00
Dry D (2,000 D)	0.1

Vitamin mixture (milligram per 100 Gm. ration)

Thiamin	0.5
Riboflavin	0.5
Choline	200.0
Folic acid	0.5
Niacin	5.0

Ration I prepared Jan. 2, 1946; II, Jan. 28, 1946; and III, March 10, 1946.

The following data are all that are available on the two commercial rations:

DUCK STARTENA RATION

Crude protein not less than	20.0%
Crude fat not less than	3.5%
Crude fiber not more than	6.5%
Nitrogen-free extract not less than	44.0%

Ingredients: Corn meal, ground oats, wheat bran, alfalfa leaf meal, meat scrap, fish meal, soybean oil meal, liver meal, corn gluten meal, wheat standard middlings, wheat germ, riboflavin supplement, vitamin A and D feeding oils, D activated animal sterol, 2% calcium carbonate (limestone), .25% iodized salt, .01% manganese sulfate.

DUCK GROWENA RATION

Crude protein not less than	18.0%
Crude fat not less than	3.5%
Crude fiber not more than	6.0%
Nitrogen-free extract not less than	48.0%

Ingredients: Meat scrap, soybean oil meal, corn gluten meal, fish meal, liver meal, ground oats, corn meal, wheat bran, wheat gray middlings, wheat germ, riboflavin supplement, vitamin A feeding oil, D activated animal sterol, 2% calcium carbonate (limestone), .25% iodized salt, .01% manganese sulfate.

Vitamin A (alphalin*) was used to supplement these rations. The contents of one capsule (25,000 units) was dropped into the mouth the younger birds and the entire capsule was given by mouth to ducks over 10 days of age. The vitamin A was given at intervals of one to three days during the time of the experiment.

Ducks were selected from the groups at different intervals and their liver was removed immediately following decapitation. The tissue was kept frozen until the vitamin A content was determined by the antimony trichloride reaction.†

The dicumarol was given by mouth. The quantity varied; in each experiment, however, a group of ducks from one hatching was used and an equal-sized dose of dicumarol was given to each bird. The amount is recorded in each experiment.

The ducks were carefully observed during the time of the experiment for the appearance of clinical manifestations. The number that died and the time of death were recorded. The average weight of the ducks used in each experiment is given in Table I.

*Ell Lilly's preparation of vitamin A.

†These tests were made by Dr. Homer Patrick of the Ralston Purina Mills, St. Louis, Mo.

EXPERIMENTAL EFFECT OF DICUMAROL ON DUCKS FED A VITAMIN A DEFICIENT RATION

A total of 149 ducks, as shown in Table I, were used in these experiments. In Experiment A, ten ducks were used, five of which were fed the vitamin A deficient ration II and five the standard rations. When 15 days of age these birds were given daily 50, 75, 100, and 50 mg. of dicumarol. On the third day each of the five birds fed the vitamin A deficient ration was dead; the five fed the standard rations had survived.

In Experiment B, seven ducks were used, two of which were fed the vitamin A deficient ration II and five the standard ration. When 17 days of age these ducks were given daily 100 and 50 mg. of dicumarol. On the second day one of the two ducks fed the vitamin A deficient ration was dead; the five fed the standard rations had survived.

In Experiment C, twenty-two ducks were used, twelve of which were fed the vitamin A deficient ration III and ten the standard rations. When 17 days of age these ducks were given daily 50, 50, 100, 200, and 200 mg. of dicumarol. On the third day five from the group of twelve fed the vitamin A deficient ration were dead, while only one from the group of ten fed the standard rations had died. On the sixth day ten ducks from the group of twelve fed the deficient ration were dead; nine were dead from the group of ten fed the standard rations.

In Experiment D, twenty-two ducks were used, twelve of which were fed the vitamin A deficient ration III and ten the standard rations. When seventeen days of age these birds were given daily 100, 100, 150, 200, and 200 mg. of dicumarol. Six hours following the first dose of dicumarol five ducks from the group of twelve fed the deficient ration were dead while only one had died in the group fed the standard rations. On the fourth day eleven of the twelve ducks fed the deficient ration had died, while seven were dead from the group of twelve fed the standard rations.

In these four experiments, seventeen ducks (54.8 per cent) were dead by the third day from the group of thirty-one fed the vitamin A deficient rations. Only four (13.3 per cent) were dead from the group of thirty ducks fed the standard rations for an equal period.

EFFECT OF DICUMAROL ON DUCKS GIVEN A HIGH VITAMIN A RATION

In this experiment, forty-five ducks were used.

In Experiment E, eight ducks were fed the standard rations supplemented with vitamin A, while ten ducks were fed only the standard rations. On the eighteenth day these birds were given daily 100, 150, 150, 150, and 150 mg. of dicumarol. Six hours following the second dose of dicumarol five of the ten ducks fed the standard rations had died, while only two from the group of eight fed the standard rations supplemented with vitamin A were dead.

In Experiment F, nineteen ducks were used, ten of which were fed the standard rations, while nine were fed the standard rations supplemented with vitamin A. On the eighteenth day of the experiment these ducks were given daily 150 mg. of dicumarol for five days. Six hours after the first dose of dicumarol was given six of the ten ducks on the standard rations had died, while only three from the group of nine on the standard rations supplemented with vitamin A were dead.

In Experiment G, eight ducks were used, four of which were fed the vitamin A deficient ration I and four the same deficient A ration supplemented with vitamin A. On the twenty-eighth day of the experiment these birds were given daily 250 and 300 mg. of dicumarol. On the second day three of the

four ducks fed the standard ration were dead; neither of the four birds fed the vitamin A deficient ration supplemented with vitamin A died.

Experiments E and F show that ducks given large amounts of vitamin A are more resistant to the acute action of dicumarol than birds of similar age fed the standard rations. In the former group seventeen ducks were used and in the latter twenty. On the third day five ducks (29.4 per cent) had died from the group fed the standard rations supplemented with vitamin A, while fourteen (70 per cent) were dead from the group fed only the standard rations.

EFFECT OF DICUMAROL ON DUCKS GIVEN A LARGE, MEDIUM, AND LOW QUANTITY OF VITAMIN A

In these experiments a total of forty-three ducks were used. To obtain ducks with the smallest amount of vitamin A, the vitamin A deficient rations were fed. The standard rations were fed to obtained birds with a medium quantity of vitamin A, while those with the largest quantity of vitamin A were fed the vitamin A deficient ration III supplemented with large amounts of vitamin A.

In Experiment H, thirty-six ducks were used. Three groups of twelve birds each were given one of the three rations as previously stated to obtain the three different levels of vitamin A. On the eighteenth day these ducks were given daily 100, 100, 100, 150 and 150 mg. of dieumarol. On the third day five ducks had died from the group fed the vitamin A deficient ration, five were dead from the group fed the standard rations, while only one had died from the group of twelve ducks fed the vitamin A deficient ration supplemented with vitamin A.

In Experiment I, seven ducks were used. Three of these ducks were fed the vitamin A deficient rations I and II, three were fed the vitamin A deficient rations supplemented with vitamin A, and one duck was fed the standard rations. On the fortieth day of the experiment the seven ducks were given 300 mg. of dieumarol daily for two doses. On the second day two of the three ducks fed the vitamin A deficient rations were dead; one of the three birds given the vitamin A deficient ration supplemented with vitamin A was dead; and the one bird fed the standard rations during this time survived the effects of the dieumarol.

In these two experiments fifteen ducks were fed the vitamin A deficient rations and given dieumarol; from this group seven (46.6 per cent) died. Fifteen ducks were fed the vitamin A deficient ration supplemented with vitamin A and two (13.3 per cent) died. Thirteen ducks were fed the standard rations and five (38.4 per cent) were dead by the third day.

The respiratory rate was greatly increased within two or three hours after the larger doses of dieumarol were given. This increase in the respiratory rate persisted for two or three hours during which time many of the ducks died. The ducks that survived the first large dose of dieumarol showed less severe clinical reaction on subsequent days to the same amount of dieumarol. The ducks that died appeared to be in satisfactory condition until a few minutes before death except for their rapid respiration. During the last few minutes

of life these dicumarol-treated ducks usually had one or more convulsions. Hemorrhages usually were absent in these ducks that succumb after the second and third dose of dicumarol. Some bleeding was present, however, in the tissues of the ducks that died on the fifth and sixth days of the experiment.

VITAMIN A CONTENT OF THE LIVER OF DUCKS

Samples from the groups of ducks were taken to determine the amount of vitamin A present in the liver. On the eighteenth day the liver from two ducks fed the vitamin A deficient ration I showed 1.5 and 14.4 U.S.P. units per gram of liver. This same deficient ration was given two other ducks and vitamin A was used to supplement it. The liver from these two ducks showed, respectively, 1,360 and 1,520 U.S.P. units per gram of liver. Two ducks were fed the vitamin A ration III and on the eighteenth day the liver from each was removed. Neither of these two birds had any vitamin A in the liver. Two ducks fed the standard rations for eighteen days had, respectively, 13.8 and 18.2 U.S.P. units of vitamin A per gram of liver tissue. The vitamin A deficient ration III was supplemented with vitamin A and fed to two ducks for eighteen days. One duck had 582 and the second 546 U.S.P. units of vitamin A in the liver.

WEIGHT OF VITAMIN A DEFICIENT DUCKS

The following is the average weight of groups of ducks fed the vitamin A deficient ration III, vitamin A deficient ration III supplemented with vitamin A, and the standard rations:

DUCKS	AGE IN DAYS	RATION	AVERAGE WEIGHT (GM.)
24	15	Vitamin A deficient ration	425
20	15	Standard rations	442
12	18	Vitamin A deficient ration	496
12	18	Vitamin A deficient ration plus vitamin A	500
12	18	Standard rations	584
28	20	Vitamin A deficient ration	623
20	20	Vitamin A deficient ration plus vitamin A	516

Ducks fed the vitamin A deficient rations usually were slightly lighter than those kept on the standard rations. The variation in weight of the different groups, however, was not very great.

DISCUSSION

The observation that ducks fed large amounts of vitamin A are relatively resistant to large doses of dicumarol is interesting since vitamin A is stored in the liver and dicumarol has been found to produce necrosis in the liver of laboratory animals.^{1,6} Apparently the mechanism has not been established for the development of hepatic necrosis following large doses of dicumarol. This action occurs, however, before the hypoprothrombinemia.¹ No specific pathologic changes have been observed in the liver of ducks given large doses of dicumarol for as long as five days. The cause of the acute death in these ducks is not known. It has been observed, however, that a 50 per cent decrease

may occur in the number of red blood cells within two to four hours following the oral administration of large doses of diemmarol. The plasma at this time does not show any hemolysis; the decrease in the hematocrit reading seems to parallel the decrease in the number of red cells. The carbon dioxide content of the plasma is approximately the same as that of normal birds. There is a decrease, however, in the carbon dioxide-combining power of the plasma of diemmarol-treated birds.¹² Experimental observations in our laboratory show that ducks fed the vitamin A deficient ration show no significant variations from the normal in the carbon dioxide content and the combining power of their plasma.

Since the reserve of vitamin A in the liver is low in certain hepatic diseases, it may be advisable to be cautious in the use of diemmarol in the treatment of such individuals if the experimental results as observed in this study should be duplicated in man. Organic and functional changes have been observed in the liver associated with deficiencies other than vitamin A. In chronic vitamin B complex deficiencies functional and fatty changes have been described.^{13, 14} A decrease occurs in hepatic function when dogs are fed a black tongue diet.¹⁵ The recent observations of Brunshwig and associates^{16, 17} are interesting in that they have shown that both thioglycollic and glycollic acids afford a degree of protection against hepatic cell necrosis due to dietary deficiency and to carbon tetrachloride in the rat. "The results with thioglycollic and glycollic acids are of interest since by their use it would appear that the lipotropic factor and necrosis protecting factor are shown not to be necessarily identical."¹⁷

It is obvious that the amounts of diemmarol used in these experiments are greatly in excess of those used therapeutically in man; in preliminary experiments, however, it was ascertained that doses of this magnitude were required to obtain the results described. There may be no relation between these experimental studies and the reactions which occur in man. However, the observation that vitamin A deficient ducks are more susceptible to the lethal effect of diemmarol seems of scientific interest.

SUMMARY

The susceptibility of ducks to the acute lethal effect of diemmarol is influenced by the intake of vitamin A. Birds fed a ration supplemented with vitamin A are more resistant to the acute lethal effects of diemmarol than birds fed a ration low in vitamin A. The mechanism by which this effect occurs is not known.

SOME FACTORS AFFECTING THE SUSCEPTIBILITY OF RATS TO VARIOUS BARBITURATES

THE EFFECT OF AGE AND SEX

E. HOMBURGER AND B. ETSTEN, ALBANY, N. Y., AND H. E. HIMWICH,
EDGEWOOD ARSENAL, MD.

THE evidence concerning the susceptibility of rats to pentobarbital sodium in regard to age and sex is controversial. Fitch and Tatum,¹ using a dose of 75 mg. per kilogram as the L.D.₅₀ for rats when injected intraperitoneally, concluded that there is no appreciable difference in the susceptibility of the females and males. But Moir² found that the anesthetic responses varied with sex and age as growth proceeded: at first, a greater resistance in the female was seen; later, this was followed by an equality in the response of the two sexes; finally, in the older rats, the male was consistently more resistant. Nicholas and Barron³ also pointed out that adult females subjected to sodium amytal were affected more than males; in addition they observed that immature rats require a lower dose of this drug to produce anesthesia than do adult rats. In agreement with these workers, Etsten and associates⁴ reported that newborn rats are more susceptible to pentobarbital than are adults, while Carmichael⁵ noted that the median lethal dose of pentobarbital is less for old rats weighing 150 to 325 grams than for young animals weighing 25 to 260 grams. In the present investigation an attempt was made to re-examine this question with the hope of resolving these contradictions.

METHODS

Three different strains of rats were employed: one from our own colony (C), another from that of the Department of Anatomy (A), and a third from the Rockland Company (R). Unless otherwise indicated in the tables in this paper, rats from our colony were used. The females were nonpregnant. All rats were kept on adequate diets, but food was withheld fifteen or sixteen hours before injecting the drugs, though water was always available.* All barbiturate solutions were freshly prepared and were never older than three hours. The observations were made at 29° Centigrade. The sex, age, weight, strain of rats, rates of injection, and concentration of solutions are presented in the tables.

The criteria used to estimate whether the anesthesia was deep or light were the ear reflex and the posture of the animal. For the ear reflex the response of the pinna is tested with a feather cut to a fine point and inserted into the ear canal. The postural reaction is indicated by the side position, when the rat cannot assume the normal posture due to loss of the righting reflex. The

From the Departments of Physiology and Pharmacology and Anesthesia, Albany Medical College, Albany, N. Y., and the Medical Division, Army Chemical Corps, Edgewood Arsenal, Md. Received for publication, Jan. 15, 1947.

*The newborn rats were not fasted. Immediately before injection they were taken away from their mothers. To prevent intraperitoneal injection, a sphygmometer clamp was placed on the point of the needle was withdrawn. This clamp was taken off after five minutes. of the animals which died did so in ten to thirty minutes. Few deaths occurred after three hours with the doses used, and the newborn were returned to their mothers after the three-hour period.

absence of the ear reflex occurs only during deep surgical anesthesia. The interval after the ear reflex has returned, but before the righting reflex is restored, measures the period of light anesthesia.

RESULTS AND DISCUSSION

It is shown in Table I that rats weighing 50 to 100 grams each (four to six weeks old) yield results which vary only within the error of the method in regard to the influence of sex. In the weight range of 101 to 200 grams, however, a sharp increase is observed in the duration of sleep in the females, an increase which is pronounced even at the low dose of 50 mg. per kilogram and which is still more marked with higher doses (Fig. 1). At 90 mg. per kilogram, nine of twenty-nine females died, while only

Fig. 1.—Effect of sex on duration of anesthesia. Comparative durations of side position, that is, total period of anesthesia, are presented diagrammatically. Female rats remain anesthetized for a longer period than male animals, after receiving an intraperitoneal injection of pentobarbital (1 per cent solution).

two of twenty-seven males succumbed. In the older group of rats weighing 201 to 350 grams, deaths occur even at 50 mg. per kilogram. At this dose, eleven of forty-eight males and sixteen of thirty females died. In every instance the duration of the narcosis is longer in the female than in the male. When 70 mg. per kilogram was administered to nineteen females in this weight group, all of them died (Fig. 2). Finally, although injection of the oldest males (351 to 500 grams) with 50 mg. per kilogram of pentobarbital resulted in a somewhat lower incidence of mortality (thirteen of sixty-three died) than in the group of males weighing from 201 to 350 grams, the duration of anesthesia was increased

*Dose of pentobarbital administered.

†Each fraction represents the incidence of mortality; the numerator indicates the number of animals that died and the denominator the total number of animals used.

by 22 per cent. It would have been desirable to inject more male rats in the weight range of 201 to 350 grams, but they were not plentiful in our colony. Fitch and Tatum¹ give 75 mg. per kilogram as the L.D.₅₀ for pentobarbital. Because the age and sex of these rats were not stated, we may point to Table I to show that this figure may be derived by employing both male and female rats weighing from 201 to 350 grams.

Fig. 2.—Effect of weight and sex on resistance to pentobarbital. Presented in diagrammatic form is the survival percentage, that is, resistance of male and female rats to three different doses of pentobarbital, namely, 50, 70, and 90 mg. per kilogram. The largest of these three doses shows most clearly that the resistance is lowest in the newborn, reaches a maximum sometime while the weight changes from 50 to 100 grams, and then recedes. But even with the lower doses the increasing susceptibility of the aged rats is seen.

Moir² observes that in male and female rats weighing about 45 grams each there is a slightly greater resistance in the females. This difference becomes marked when the female rats weigh 55 grams and the male rats 59 grams. This stage of greater female resistance is followed by another in which there is no appreciable difference between the two sexes. This period in which both sexes respond in the same way takes place while the female rats grow from 63 to 81 grams and the male from 68 to 85 grams. After that the relation between the male and female is the opposite of the earlier reaction, for the males become more resistant. The comparatively diminished female resistance is even further impaired when the females weigh 104 grams and the males 113 grams. Thus, the similarity between the reactions of the male and female rats weighing from 50 to 100 grams may be explained by Moir's work as including three periods: (1) greater female resistance, (2) no difference between sexes, and (3) greater male resistance.

It is shown in Table II that a difference in susceptibility is observed even among newborn rats if they are grouped according to weight. The larger and more vigorous newborn rats can tolerate a greater amount of the drug. Yet, with doses of 70 mg. per kilogram or more (results not included in Table II) the mortality is 100 per cent, even with the heaviest members of the newborn group. Irrespective of the differences among the newborn as a group, they are more sensitive to barbiturates than are the adults.

TABLE II. EFFECT OF INTRAPERITONEAL PENTOBARDITAL ON RATS LESS THAN TWENTY-FOUR HOURS OLD

WEIGHT RANGE (GRAMS)	DOSE (30 MG./KG.)	DOSE (40 MG./KG.)	DOSE (50 MG./KG.)
4 to 4 $\frac{1}{4}$	5/7*	6/7	1/1

6 to 6 $\frac{1}{4}$	3/19	4/24	4/6

In order to maintain the same small volume of injection, the concentrations were varied: 30 mg. per kilogram, 0.15 per cent; 40 mg. per kilogram, 0.20 per cent; and 50 mg. per kilogram, 0.25 per cent.

*Each fraction represents the incidence of mortality; the numerator of fraction indicates the number of animals that died and the denominator the number of animals used.

It is generally accepted that a reciprocal relation exists between metabolic rate and narcotic effect. In the present investigation it has been possible to push this analysis one step further, and it is suggested that this relationship rests for the most part on the metabolic rate of the brain rather than that of the entire body. It is true that in rats the form of the curves for basal metabolic rate⁶ and cerebral metabolic rate⁷ are similar on a basis of age. Both curves fluctuate within their lowest levels for approximately the first three weeks of life before rising rapidly to a maximum at the end of the seventh week and then receding very slowly toward old age. However, the early changes of basal metabolism rate would seem to depend on the entire organism rather than on the metabolism of any organ, for the metabolism of kidney and liver slices from newborn rats is found to be approximately the same as in the mature animal.⁸ Cerebral metabolism, on the contrary, is much lower in the newborn than in the adult,⁷ an observation which may explain the lessened resistance of the neonate to barbiturate. This relationship between cerebral metabolism rate and narcosis is to be expected since the primary effect of narcosis is exerted on the brain.

Tables III and IV represent a comparative study of pentothal and compound 897 (N-methyl-pentobarbital).^{*} With strain A, but not with the other strains, the intravenous M.L.D. for a male rat weighing 360 to 460 grams is 50 mg. per kilogram for pentothal and 40 mg. per kilogram for compound 897.

†Each fraction represents the incidence of mortality; the numerator indicates the number of animals that died and the denominator the total number of animals used.

These results emphasize that differences in the strains of rats and especially in weight (age) are important factors in the responses to the barbiturates. It should also be pointed out that recovery, especially with the higher doses, is much faster with compound 897 than with pentothal.

An interesting difference appears (Table V) between the reactions to a single intravenous injection of the three barbiturates: pentobarbital, pentothal, and compound 897. In these observations the ages of the male and female members of a test group are the same as are the doses in terms of weight. The exact dosage chosen, however, is arbitrary, since 30 mg. per kilogram of pentothal is approximately 60 per cent of its M.L.D. and is 75 per cent of the M.L.D. of compound 897. Nevertheless, the recovery from anesthesia is faster with the latter compound.

Pentobarbital and compound 897 show a difference in the reactions between the two sexes, for the female rats exhibit longer periods of deep and total anesthesia than do the male animals, while with pentothal such a differentiation fails to appear. Similar preliminary observations made on dogs disclose that these animals do not exhibit the sexual differences to compound 897 which are noted in rats. The causes for these characteristic responses of male and female rats to pentobarbital and to compound 897 have not been elucidated, except to the extent that Moir² found that the discrepancy diminishes but does not disappear after castration of the male rats. Similarly, the injection of testosterone propionate into female rats cuts down the period of anesthesia significantly.⁹

Data from this laboratory on thiamine-deficient dogs¹⁰ suggest that they exhibit a reduced resistance to pentobarbital, in comparison with animals on a complete diet. Such an impairment of resistance previously has been reported for rats.¹¹ Pentobarbital becomes more effective not only in animals with thiamine deficiency but also in those with a deficiency of ascorbic acid.¹² We may conclude that in addition to age, sex, weight, strain, and species, diet is also an important factor in determining the responses to barbiturates.

TABLE V. INTRAVENOUS INJECTION OF THREE BARBITURATES (1 PER CENT SOLUTION)

COMPOUND	SEX	AGE IN MONTHS	WEIGHT RANGE (GRAMS)	INJECTION TIME IN MINUTES	DOSE MG./KG.	NUMBER OF ANIMALS INJECTED	NUMBER OF ANIMALS SURVIVED	EAR REFLEX ABSENT (MINUTES)		SIDE POSITION MAINTAINED (MINUTES)	
								AVERAGE	RANGE	AVERAGE	RANGE
Pentobarbital	M	2	170 to 230	1/2	40	9	9	62	40 to 86	118	81 to 155
	F	2	130 to 170	1/2	40	9	9	100	35 to 130	238	180 to 340
Pentothal	M	3	260 to 310	1/2	30	9	9	10	8 to 28	32	16 to 81
	F	3	160 to 200	1/2	30	9	9	15	8 to 20	26	15 to 40
Compound 897	M	3 1/2	260 to 340	1/2	30	7	7	14	8 to 20	38	22 to 71
	F	3 1/2	170 to 230	1/2	30	8	8	45	15 to 72	146	53 to 232

SUMMARY AND CONCLUSIONS

Age, weight, sex, strain within a given species, difference in species, diet, and kind of barbiturate, all influence the reaction to this group of drugs.

1. The newborn rat, not more than twenty-four hours old, is more susceptible than is the adult, while rats weighing 50 to 200 grams are less susceptible than are those weighing 201 to 500 grams. It is possible therefore to form a spectrum of resistance lowest in the newborn, maximum in rats weighing from 50 to 200 grams, and intermediate with advance in weight and age.

2. As growth proceeds the first increase in the greater susceptibility of the female to pentobarbital is observed in rats weighing 101 to 200 grams, for in that weight range the female remains in light anesthesia longer, though the lethality is the same for both sexes. In rats weighing 201 to 500 grams and receiving pentobarbital, not only is the duration of narcosis longer in the female but the lethality is greater.

In response to an intravenous injection both pentobarbital and compound 897 produce more pronounced effects in the female than in the male, but pentothal exhibits no sexual difference.

3. The intravenous M.L.D. for male rats weighing 360 to 460 grams is 50 mg. per kilogram for pentobarbital and 40 mg. per kilogram for compound 897.

A more rapid recovery from anesthesia follows the administration of compound 897 than follows dosage with pentothal.

4. Differences in the reaction to barbiturates are noted in three strains of rats.

LABORATORY METHODS

A SIMPLIFICATION OF THE SEROLOGIC DIAGNOSIS OF SALMONELLA CULTURES

F. KAUFFMANN AND P. R. EDWARDS
LEXINGTON, Ky.

RECENTLY, the attention of many workers has been drawn to the *Salmonella* group by numerous publications on the genus. This increased interest in a group recognized for many years is due to several factors: A rise in enteric infections caused by large movements in population and the makeshift living conditions of the war years, improved methods of isolation of the bacteria, and, finally, the fact that rapid and reliable methods of identification of cultures by serologic analysis are now available.

Faced by a greater demand for accurate diagnosis of enteric infections and his own ability to isolate a larger number of intestinal pathogens by the use of improved selective media, the worker in the average laboratory has been placed at a disadvantage by inability to identify the cultures which are isolated. The multiplicity of *Salmonella* types and the many sera necessary for their exact identification have prevented workers in small laboratories from taking advantage of the newer knowledge of *Salmonella* serology. Thus, many laboratories still depend upon agglutination tests in which the O and H reactions of the cultures are not distinguished and the phases of the H antigens are not considered. Such a system inevitably leads to errors in diagnosis which may seriously handicap the work of the epidemiologist.

It is highly desirable that exact methods of identification of the principal pathogens among the *Salmonella* and approximate methods of diagnosis of the remaining types be made available in simplified form. The public health laboratory should be able to identify with certainty *S. paratyphi A*, *S. paratyphi B*, *S. paratyphi C*, *S. typhi*, and *S. scudai*, since these are strictly human types which produce prolonged febrile diseases, result in a relatively high carrier rate, and tend to become endemic in the population. *S. choleraesuis* also should be identified exactly because it frequently produces septicemia with localizations in man. Finally, it is desirable to identify *S. typhimurium* since it occurs more frequently in man than any other of the numerous types which produce acute gastroenteritis.

Laboratories engaged in the study of diseases of the domestic animals should be able to identify the so-called primary salmonellosis; *S. abortus equi* in horses, *S. dublin* in cattle, *S. abortus ovis* in sheep, *S. choleraesuis* in hogs, and *S. pullorum* and *S. gallinarum* in fowls. Here again it is desirable that

From the State Serum Institute, Copenhagen, and the Department of Animal Pathology, Kentucky Agricultural Experiment Station.
Received for publication, Feb. 5, 1947.

S. typhimurium be identified exactly since it occurs so frequently in all animal species. The remainder of the numerous types which occur in domestic animals may be separated into their respective groups but may not be subjected to exact type determination.

Fortunately, the vast majority of *Salmonella* strains isolated from man and animals are members of groups A, B, C, D, and E of the Kauffmann-White classification. In 1943 Edwards and Bruner² found that 98.3 per cent of 3,019 cultures from man and animals were members of these five groups. In 1946 Seligmann, Saphra, and Wassermann⁸ obtained an identical figure in 2,916 cultures from man. In 1947 Bruner and Joyce¹ classified 99.5 per cent of 1,007 cultures from man in these groups. Unpublished data of Edwards and Bruner on 12,000 cultures isolated from man and animals indicate that more than 97 per cent of the strains are found in the five previously mentioned groups. Thus, it is evident that the average laboratory need concern itself only with the identification of *Salmonella* cultures which are members of five somatic groups.* Other cultures occur so rarely that they may be forwarded immediately to a laboratory which specializes in the study of the genus.

Considering these facts, we propose the following diagnostic scheme for the average routine laboratory. A polyvalent serum which contains agglutinins for antigens I, II, III, IV, V, VI, VII, VIII, IX, X, XII, and XV should be available. This is prepared by injecting a rabbit with a mixture of equal amounts of boiled broth cultures of *S. paratyphi A*, *S. paratyphi B*, *S. thompson*, *S. newport*, *S. gallinarum*, *S. anatum*, and *S. newington*. Details of the preparation of polyvalent sera were published in 1942 by Kauffmann.⁷

Five O sera for groups A to E, respectively, should be prepared as follows:

A	I,II,XII	<i>S. paratyphi A</i>
B	IV,V,XII	<i>S. paratyphi B</i>
C	VI,VII,VIII	<i>S. thompson</i> and <i>S. newport</i>
D	IX,XII	<i>S. gallinarum</i>
E	III,X,XV	<i>S. anatum</i> and <i>S. newington</i>

Methods of preparation of these sera were given in 1941 by Kauffmann⁶ and in 1942 by Edwards and Bruner.² It will be noted that groups C₁ and C₂ are represented by only one serum as are also groups E₁ and E₂. In this way the number of necessary sera is reduced.

For the public health laboratory a Vi serum is needed to aid in the identification of *S. typhi* and *S. paratyphi C*. This may be made from a living or an alcohol-treated culture of *S. ballerup* by the method of Edwards and Bruner² (1942). Such a serum contains agglutinins for O antigen XXIX and H antigen z₁₄, in addition to Vi, but these antigens occur so rarely that the serum may be used without absorption for the determination of Vi antigen.

*As early as 1930 Kauffmann (Die Technik der Typenbestimmung Typhus-Paratyphusgruppe, Zentralbl. f. Bakt. [Abt. 11] 119: 152, 1930) set of 12 OH sera by which the common members of groups A to E could be identified 1942 a similar proposal was made by Bornstein (Practical Suggestions for determination of *Salmonella* Organisms, J. Bact. 44: 719, 1942.)

The public health laboratory should have six II sera as follows:

a	<i>S. paratyphi A</i>
b	<i>S. huttingfoss</i> , phase 1 (or <i>S. paratyphi B</i> , phase 1)
c	<i>S. choleraesuis</i> , phase 1
d	<i>S. typhi</i>
i	<i>S. aberdeen</i> , phase 1 (or <i>S. bonariensis</i> , phase 1)
1,2,3,5	<i>S. thompson</i> , phase 2, and <i>S. newport</i> , phase 2

Workers in animal pathology should have the c, i, and 1,2,3,5 sera and, in addition, the following:

c,n,x	<i>S. abortus equi</i>
g,p	<i>S. dublin</i>

The preparation of II sera was described in 1941 by Kauffmann⁶ and in 1942 Edwards and Bruner.²

With this modest array of sera and by use of the ordinary biochemical tests it is possible to identify the principal *Salmonella* types and to group practically all *Salmonella* cultures.

The polyvalent serum is used in slide agglutination tests, usually in a dilution of 1:5 or 1:10, depending upon the titer of the particular serum. It can be used to test colonies directly from plates of selective media or to test growth from slants of differential media to which colonies are transferred. A bit of growth is mixed in saline on a slide and an equal amount of polyvalent sera added or, if desired, the growth may be emulsified directly in the serum dilution. Agglutination becomes apparent after the slide is tilted back and forth for thirty seconds to one minute. In dealing with cultures from man the Vi serum should be used in conjunction with the polyvalent serum so that O-inagglutinable cultures of *S. typhi* will not be missed. If agglutination is not obtained thus with growth from any of the suspicious colonies, those which yield growth resembling *Salmonella* on differential media should be carried through the usual biochemical tests to eliminate the presence of rare *Salmonella* types. If the biochemical tests indicate that the organisms are *Salmonella*, they should be sent to a center for identification.

If agglutination occurs in Vi serum, *S. typhi* should be suspected. In the event that agglutination occurs in the polyvalent serum but in Vi serum, it is probable that a *Salmonella* other than *S. typhi* is present. Cultures which agglutinate in the polyvalent serum should be tested in a similar manner with the sera for the various O groups. While some cross-agglutination occurs between the different O groups, the reactions are usually quite distinct so that no difficulty is encountered in determining to which O group a culture belongs. Cultures which agglutinate in Vi serum should be heated in saline at 100° C. for a few minutes and tested with the O sera. Thus, the *Salmonella* strains can be divided into their respective O groups. Cultures which are initially agglutinable by Vi serum after heating should fall into group C if they are *S. paratyphi C* and into group D if they are *S. typhi*. If no agglutination occurs in the O sera after heating, the heated culture should again be tested in Vi serum.

If agglutination still occurs, it may be concluded that the culture contains XXIX antigen and is not a member of any of the common groups. Very rarely rough cultures of *S. typhi* are isolated which will not agglutinate with group D serum after heating. Thus, it is necessary to determine by biochemical methods whether cultures, which in the living state agglutinate in Vi serum but after heating are inagglutinable by group C, group D, and Vi sera, are in reality rough cultures of *S. typhi*.

After the O group of the culture is determined its H antigens should be examined. This may be done by testing growth from an agar slant on a slide with H sera which are diluted 1:50 or 1:100. An alternate method is that recommended in 1942 by Edwards and Bruner,³ in which an infusion broth culture is diluted with an equal amount of saline containing 0.6 per cent formalin and tested with appropriate sera at 50° Centigrade. Only one dilution (1:1000) is used and results are read after incubation for one hour in a water bath.

In dealing with cultures from man the group A cultures should be tested with serum a to assure that they are *S. paratyphi A*, the only known type in that group. In addition, they should be subjected to the differential tests, non-fermentation of xylose, and inability to utilize tartrates and citrate. The majority of *S. paratyphi A* strains produce little or no H₂S.

Group B cultures should be tested with H sera, b, i, and 1,2,3,5. In the event that agglutination occurs in b or i serum, the culture is almost certainly *S. paratyphi B* or *S. typhimurium*, respectively. Diphasic cultures often occur only in one phase when recently isolated. If phase 2 only is present, it is necessary that phase 1 be obtained to identify the culture. Thus, if the culture is agglutinated only by 1,2,3,5 sera, it should be planted on a Gard plate (Kauffmann,⁶ 1941) with 1,2,3,5 serum or placed in a tube containing 2 or 3 c.c. of semisolid medium to which a loopful of that serum has been added. Phase 1 will migrate through the medium and can be isolated from the spreading growth. Useful modifications of the Gard technique have been described by Edwards and Bruner² (1942), Hajna⁴ (1944), and Juenker⁵ (1946). After phase 1 is obtained it can be determined whether the culture is *S. paratyphi B*, *S. typhimurium*, or some other type within group B.

Group C cultures should be tested with c and 1,2,3,5 sera. If agglutination occurs in c serum, the culture may be identified as *S. paratyphi C* or *S. choleraesuis* depending upon its biochemical reactions. *S. paratyphi C* usually ferments arabinose and always ferments trehalose promptly whereas *S. choleraesuis* attacks neither of these sugars. *S. paratyphi C* ferments dulcitol promptly while *S. choleraesuis* gives delayed or negative reactions in dulcitol media. If phase 2 only is present, phase 1 should be isolated as previously described and tested with c serum. It should be remembered that the majority of cultures of *S. choleraesuis* belong to the Künzendorf variety in which phase 1 is more or less completely suppressed, so that any group C culture which agglutinates 1,2,3,5 serum, fails to ferment arabinose and trehalose, and gives a negative or delayed result in dulcitol may be reported as *S. choleraesuis*.

Group D cultures should be tested in a, d, and 1,2,3,5 sera. Cultures which agglutinate only in d serum, which are anaerogenic, and which possess the usual biochemical attributes of *S. typhi* may be reported immediately. The organism will have been examined already for the presence of Vi antigen so that its identity is fairly well established. Some recently isolated cultures of *S. typhi* are very poorly motile and may fail to flocculate in d serum. Such cultures can be typed as *S. typhi* provided they possess IX, XII, and Vi antigens and the biochemical properties of *S. typhi*.

Identification of *S. sendai* depends upon the recognition of both phases and biochemical examination. It is necessary that the organism agglutinate both in a and 1,2,3,5 sera. If only one phase is present the second must be isolated as previously described. Further, this type is H₂S and citrate negative and gives a negative result in Stern's glycerol-fuchsin broth. Arabinose is fermented immediately but xylose and sorbitol give delayed reactions. Cultures with similar antigens but different biochemical reactions belong to another type. *S. sendai* occurs frequently only in the Orient.

Cultures which belong to group E are not examined further but are recorded simply as group E *Salmonella*.

Cultures of animal origin are treated in much the same manner as human cultures. Group A cultures are known to occur only exceptionally in animals and need not be considered. Group B cultures are tested with c; c,n,x; i and 1,2,3,5 sera. *S. abortus equi* should agglutinate only with c,n,x serum and when planted in semisolid medium containing c,n,x serum it should fail to spread since this type is monophasic. Both phases of *S. abortus ovis* should be recognized. This type should agglutinate in c and 1,2,3,5 sera. Further, the organism should fail to ferment trehalose. It is characterized by a more delicate growth on agar media than that exhibited by most *Salmonella*. *S. typhimurium* is identified as previously described.

Group C cultures are treated as are human strains of group C in order to identify *S. choleraesuis*.

Motile strains of group D are tested with g,p serum to determine whether they are *S. dublin*; *S. enteritidis* also will agglutinate with this serum, but typical Dublin strains can be differentiated from *S. enteritidis* by the fact that *S. dublin* gives a negative or delayed test with arabinose while *S. enteritidis* ferments the sugar promptly.

Nonmotile strains of group D are probably *S. gallinarum* or *S. pullorum*. Such cultures which are anaerogenic and which promptly ferment dulcitol and maltose may be classified as *S. gallinarum*. *S. pullorum* is usually aerogenic but anaerogenic strains occur. Typical cultures ferment neither maltose nor dulcitol although maltose-fermenting strains occasionally are found. Nonmotile cultures which fail to ferment dulcitol may be classified as *S. pullorum*. This type is also characterized by its sparse growth on artificial media.

In summary, it is hoped that through the adoption of a system similar to that previously described, a more satisfactory diagnosis of *Salmonella* types may be achieved in the routine laboratory. Such laboratories should not attempt to type every *Salmonella* culture but should identify exactly only the more

important types. The remaining cultures should be designated "Salmonella, type undetermined" and sent to a center for identification. The adoption of such a system will permit the rapid diagnosis of 98 per cent of Salmonella infections. At present many laboratories still rely on ordinary agglutination tests with sera of doubtful authenticity and specificity and upon biochemical reactions. Reports on Salmonella cultures are therefore often long delayed and inaccurate.

It is realized that this proposal is not strikingly original and that any proposal short of complete typing must be a compromise. However, the system is flexible and can be modified to suit the needs of the individual. The methods proposed here are based upon our experience, with a view toward the employment of a minimal number of sera.

THE PROTHROMBIN TIME AND VARIABLES IN THE METHOD

JOHN W. MARTIN, M.D., GEORGE H. CURFMAN, JR., M.D., AND FRANK L. CAVANO
CLEVELAND, OHIO

THE prothrombin test as originally devised by Quick¹ and subsequently modified by Link,² Shapiro,³ Brambel,⁴ and others is steadily becoming more important in clinical medicine, particularly as a guide to dicumarol therapy. Accurate, consistent results are imperative if patients are to be adequately treated yet not unnecessarily subjected to the danger of serious hemorrhage. Indeed, if dependable prothrombin values are not obtainable, dicumarol therapy must be discarded.

Our own early experience and observations of some other laboratories lead us to believe that prothrombin results are very often dangerously inaccurate. In the course of our work some factors causing variations have been found. Some have not been mentioned previously and others have received too little emphasis. It is hoped that the recognition of some of the pitfalls may be of value to others and of help in the development of a more reliable technique.

THE PROTHROMBIN TEST—DESCRIPTION OF TECHNIQUE

All one-stage prothrombin tests used today are based on the original method of Quick. We have followed the Brambel modification of the Quick test because it is more accurate in determining early changes in prothrombin content. This is particularly true between 35 and 100 per cent, where the Brambel dilution curve rises more sharply than do either the dilution curves of Quick or Link and Shapiro (Fig. 1).

Regardless of the method used, each laboratory should determine its own dilution curve in order to report accurately in per cent of prothrombin. Variations in the strength of the thromboplastin and other factors that will be considered later make it impossible to read results from dilution curves that have been made in other laboratories. In the following outline of the method, we follow closely the Brambel technique⁴ and note its variations from Quick.

Thromboplastin is prepared from rabbit brain according to the method described by Brambel.⁴ It is then kept in a desiccator at 4° C. or sealed in vacuum bottles and kept in the refrigerator. When ready for use, the dried brain containing the thromboplastic substance is removed from the vacuum tubes or the desiccator and ground to a fine powder with a pestle and mortar. (With Quick's method the thromboplastic substance is used without any further grinding.) Then 250 mg. of this powder are suspended in 5.0 c.c. of normal saline solution (0.85 per cent) containing 0.1 c.c. of a 0.1 molar solution of sodium oxalate. After the test tube is thoroughly shaken to insure uniform

Received for publication, March 12, 1947.

distribution of the particles, it is placed in a water bath maintained at 50°C . for a period of just fifteen minutes. While in the water bath, the test tube is vigorously shaken for ten seconds every two minutes. It is important that the material be shaken regularly and consistently at the two-minute period, as the amount of agitation will change the prothrombin times obtained. Additional shaking will cause times to increase.

At the end of the incubation period the material is put in a centrifuge, and revolved at 500 r.p.m. for just twenty seconds. This will give a milky supernatant fluid which may then be pipetted off and used for testing.

Fig. 1.—Dilution curves obtained by three different methods.

Quick's method of preparation of thromboplastin differs from the previously described method of Brambel only in the following ways: (1) There is no grinding of the acetone-washed, dried brain before adding the normal saline-sodium oxalate mixture; (2) during the period of incubation the only agitation is that produced by the occasional blowing through the mixture with a pipette; and (3) 300 instead of 250 mg. of thromboplastic material are incubated in 50 c.c. of saline-oxalate mixture. This change of amount does not appear to be important, as an excess of thromboplastin is used in both methods.

Plasma for prothrombin determination is obtained by mixing 4.5 e.e. of venous blood with 0.5 e.e. of 0.1 molar sodium oxalate. This is centrifuged at 1,500 r.p.m. for twenty minutes.

One-tenth of a cubic centimeter of plasma is then placed in an 8 by 100 mm. test tube and to this is added 0.10 e.e. of thromboplastin solution. The two are thoroughly mixed and placed in a constant temperature water bath

of 37° C. for two minutes. One-tenth of a cubic centimeter of 0.025 molar calcium chloride, which has previously been allowed to stand at 37° C., is then drawn into a 1.0 c.c. pipette calibrated in 0.10 c.c. graduations to the tip. The calcium chloride is quickly blown into the plasma-prothrombin mixture and at the same moment a stop watch is started. A foot switch for the operation of the watch as described by Shapiro is helpful.³

In introducing the calcium chloride into the plasma-prothrombin mixture, it is important to keep several points in mind. The transfer must be made quickly, but care must be taken so that the solutions will not remain on the side of the tube and prevent complete mixing. The pipette used for calcium chloride must be very carefully wiped before it is used again. If this is not done, small drops of the prothrombin-plasma mixture may adhere to the sides of the pipette and contamination of the calcium chloride solution will result, invalidating further tests. A fresh pipette may be used for each transfer of the calcium chloride, but this does not seem necessary if due care is taken.

Once the solutions are mixed by shaking, the mixture is held in the water bath for ten seconds. The tube is then lifted out and gently tilted back and forth until the solution abruptly gels. When coagulation first begins, the stop watch is stopped and the time recorded to the nearest one-tenth of a second. All runs should be done in duplicate and should check within a second for undiluted plasmas.

EXAMINATION OF POSSIBLE VARIABLES IN THE METHOD

Stability of Thromboplastin in Dry State.—As others have reported, we also have found that the stored thromboplastin loses its potency when exposed to air but that the temperature factor is not so important. According to Quick,⁵ when thromboplastin is stored at 4° C. in vacuum containers, potency is maintained over a period of years.

We have tested the same dried thromboplastic substance, prepared according to the Brambel method, over a period of five and one-half months and have found no decrease in the strength. The figures in Table I give the prothrombin times obtained on the same normal individuals over a period of months. In this experiment three separate batches of thromboplastin, kept continuously in a desiccator at 4° C., were used for testing.

TABLE I. STABILITY OF DRIED THROMBOPLASTIN STORED IN DESICCATOR AT 4° C.
(FIGURES GIVE PROTHROMBIN TIME IN SECONDS)

	DATE TESTED	THROMBOPLASTIN		
		A	B	O
Normal plasma (G. C.)	June 24	17.4

Stability of Thromboplastin in Solution.—It is of some importance to know how long this thromboplastic solution maintains its strength, for time and material may be saved if its stability is such that it may be used for more than one series of tests. In Tables II and III the results of daily tests on the same individuals are shown. The thromboplastic solutions were made up fresh on the first day and kept in the refrigerator at 2° C. for the duration of the experiment. Bloods were drawn at the same time each day on the normal individuals tested, and in all respects the tests were done in the same manner each day.

In Table II are shown the daily times obtained using thromboplastin prepared in our laboratory from the acetone extraction of rabbit brain. When not used for testing, it was kept in the refrigerator. It will be noted that there is a change in potency on the sixth day. This is more noticeable in the first three cases which were done some months before the last four by a different technician and with a different lot of thromboplastin. It would appear justifiable on the basis of these data to use such thromboplastic solutions for at least four days before discarding them.

Average	15.9	16.4	16.5	18.4	17.8	17.5	19.5	18.5	19.1

In many laboratories it is not feasible to prepare thromboplastin from rabbit brain, and the use of a commercial product is necessary. We have therefore extended our observations to one, frequently used, ready-made thromboplastin (Maltine). The experiment was carried out in the same manner as previously described. In this instance there is a significant loss of strength on the fourth day, but values are consistent for the first three days (Table III).

Calcium Chloride Solution.—We have used a 0.025 molar concentration of calcium chloride. This is the same strength solution as is used by Shapiro and Brambel. Quick also previously used this solution, but has more recently

changed to a 0.020 molar strength. This may account in part for shorter times observed when using the Quick technique, as the calcium chloride concentration is a critical factor in this test.

Pohle and Stewart⁶ showed that even small variations of the calcium chloride had a distinct effect on the prothrombin time. As the calcium chloride strength was reduced to about 0.01 molar the prothrombin times became shorter. Below this level there was a rapid lengthening. We have confirmed these observations, as is shown in Fig. 2. Actually, other molarities than the usual 0.025 molar might be adopted if a dilution curve for that solution were set up and percentage values then derived from that curve. The important consideration is that the calcium chloride solution be consistently of the same strength.

Fig. 2.—Effect of calcium concentration on prothrombin time.

Solutions should be made up accurately and in large enough volume to obviate the necessity of frequent preparation of new stock solutions, which might lead to error. As anhydrous calcium chloride is most hygroscopic, its weight will change even as it is being removed from the container for weighing. For critical work a final chemical analysis of the solution is desirable.

Plasma—Collection of the Blood.—Plasma is obtained by mixing 4.5 c.c. of blood with 0.5 c.c. of 0.1 molar sodium oxalate. The mixture is then centrifuged for twenty minutes at 1,500 revolutions per minute. It is important that the vein be entered cleanly and a perfectly dry syringe be used, as slight clotting or hemolysis of the blood will cause shortening of prothrombin times (Figs. 3 and 4).

Plasma Stability.—It is usually assumed that the prothrombin test will be run soon after the blood is drawn, but there is little specific information on the stability of the plasma at various temperatures. Link² reported that normal rabbit plasma was constant in prothrombin content for several hours at room temperature but that bloods of animals eating spoiled sweet clover (dicumarol equivalent) were likely to change in value after standing three or four hours. Campbell and associates⁷ have found that no appreciable error was introduced in keeping plasma obtained from normal rabbits for a week at 0° Centigrade.

In Tables IV to VII tests have been run on both abnormal and normal plasmas, kept for varying times at different temperatures. It will be seen that although there is a more rapid deterioration of prothrombin at high temperatures than at lower ones, prothrombin stability does not vary directly nor consistently with temperature change.

Fig. 3.

Fig. 3.—Effect of hemolysis on prothrombin time.

Fig. 4.

Fig. 4.—Effect of clotting on prothrombin time.

In Table IV is shown the loss of prothrombin potency when plasmas are kept refrigerated at 1 to 2° Centigrade. Bloods were drawn at 9:30 A.M., and the plasma was immediately separated by centrifuging and placed in the ice-box. The first determinations were made one hour after bloods were drawn and the second test four hours after obtaining the specimens. There is no significant change up to four hours, but after seven hours the three normals do show definite lengthening of times. At ten hours all show evidence of weakening of the prothrombin strength. It is obviously impossible to keep plasmas overnight in a refrigerator and still obtain accurate results.

In a similar manner blood samples were obtained and the plasmas allowed to remain at a room temperature of 21° C. (70° F.). Loss of potency was not greatly accelerated as compared to plasmas kept in the icebox, but in five hours' time some samples gave evidence of slight loss of prothrombin activity. In six hours five of the eight gave longer values (Table V).

A series run during the summer months at a room temperature of 29° C. (89° F.) showed no significant variation at five and one-half hours but considerable deterioration of prothrombin activity after six and one-half hours (Table VI). It appears, therefore, that with the room temperatures usually

encountered (70 to 84° F.) there is little variation in rate at which prothrombin activity is lost.

All specimens should be run as soon as possible after the bloods are drawn, and any plasma kept longer than five hours either at room or icebox temperatures cannot be interpreted with accuracy.

When the temperature is raised to 37° C., loss of potency is much more rapid, as is shown in Table VII. This sudden rise in rate of prothrombin destruction is somewhat surprising in view of results noted at lower temperatures. We are unable to explain this variation in action. Perhaps prothrombin loss is due to the action of enzymes present in the plasma or it may be a result of bacterial activity. No attempt has been made to run these tests under strict aseptic conditions.

Plasma—Time of Taking Blood Samples.—Meyers and Poindexter,⁸ using the dilute prothrombin method of Shapiro, showed that patients with coronary arteriosclerosis had a slightly shorter prothrombin time in the evening and early morning hours. Levan⁹ states that "determinations after breakfast were considerably higher in per cent prothrombin than fasting specimens." That is, the prothrombin times after breakfast were shorter.

We have run serial determinations throughout the day on ambulatory patients. Since other work being carried on in the laboratory at this time necessitated the use of the Link-Shapiro method, it was employed in these particular determinations.

The first specimens were taken at 8:30 A.M. and breakfast was eaten immediately. A second blood was drawn at 10:30 A.M., approximately two hours after breakfast. Lunch was eaten at 11:45 A.M., and a midafternoon sample was taken at 3:00 P.M. Supper was served at 5:00 P.M., and the fourth and last blood was drawn at 11:00 P.M. We did not find any significant difference between bloods drawn before and after breakfast, and it would not appear necessary to insist on fasting blood samples. There is, however, consistent lengthening of the prothrombin times of the 3:00 P.M. samples when these are compared to morning samples. The specimens drawn at 11:00 P.M. have somewhat shorter times than those in midafternoon but are longer than morning tests (Table VIII).

TABLE VIII. DIURNAL VARIATION (MALTINE THROMBOPLASTIN) (TIME IN SECONDS)

CASE	8:30 A.M.	10:30 A.M.	3:00 P.M.	11:00 P.M.
1	14.5	15.0	15.5	15.1
2	15.5	16.0	16.5	16.2
3	15.3	15.2	16.2	15.3
4	15.2	15.2	16.8	15.9
5	15.6	15.6	18.0	17.1
6	15.2	16.2	17.2	16.2
Average	15.2	15.5	16.7	16.0

Meals at: 8:40 A.M., 11:45 A.M., and 5:00 P.M.

For maximum accuracy it is advisable to take blood samples at the same time each day. It may well be that patients on dicumarol show even wider diurnal fluctuations, but this is impossible to demonstrate, as any such change would be obscured by fluctuations in levels due to the action of the drug itself.

TABLE IX

TYPE OF MEAL	TIME OF SPECIMEN	PROTHROMBIN TIME (SECONDS)		
		PATIENT 1	PATIENT 2	PATIENT 3
Breakfast with 20 Gm. fat	Fasting	17.5	17.0	17.4
	Two hours after meal	14.7*	16.9	16.9
Breakfast with 50 Gm. fat	Fasting	17.6	17.8	17.5
	Two hours after meal	17.1	17.4	16.9

*Hemolyzed blood.

It may be that the degree of lipemia of the blood following meals may account for a slight diurnal variation. Pohle and Stewart,⁶ using the Quick method, found a shortening of times after a meal heavy with fat. We have not been able to show any difference in the undiluted times on bloods taken (1) two hours after an average breakfast containing 20 to 30 Gm. of fat and (2) those taken before and two hours after a breakfast containing 50 Gm. of fat (Table IX).

Variations in the Running of the Prothrombin Test (Quick Method or Brambel Modification).—

Water Bath Temperature: As shown in Tables X and XI, no great error is introduced if the temperature of the water bath is changed from 35 to 40° Centigrade.

TABLE X. EFFECT OF TEMPERATURE CHANGE OF WATER BATH ON PROTHROMBIN TIMES (BRAMBEL TECHNIQUE AND THROMBOPLASTIN PREPARED IN OUR LABORATORY) (TIME IN SECONDS)

TABLE XII
(PROTHROMBIN TIME IN SECONDS)

CASE	TILT TUBE METHOD	WIRE LOOP METHOD
1	21.9	21.6
2	15.7	16.1
3	24.9	24.6
4	15.9	16.7
5	24.5	24.9
6	27.2	26.8
7	15.3	15.2
8	15.0	14.5
9	16.1	15.8
10	25.2	24.4

The same lack of variation in times with changes in temperature of the water bath is also found when the Link-Shapiro method is used with maltine thromboplastin.

Use of Tilt Tube or Wire Loop Method: Some workers determine the time of clotting by passing a thin wire loop through the solution and noting when the fibrin first adheres to the wire. We have run parallel determinations on the same plasmas using this wire method and the tilt-tube technique. No consistent difference is apparent in the results shown in Table XII.

Order of Mixing Reagents: There is another variation in the running of the test that does alter the results. In the Link-Shapiro method the calcium chloride and thromboplastin are first mixed together and finally 0.10 c.c. of plasma is added just as the stop watch is started. In the Quick and Brambel methods the thromboplastin and plasma are first mixed and the calcium chloride is added last. We have found that this minor change in technique will give a consistent difference in results. When the calcium chloride is first mixed with thromboplastin and the plasma is added last, the times are shorter than when there is premixing of plasma and thromboplastin with a final addition of calcium chloride. The results of the two methods run on twelve consecutive plasmas are shown in Fig. 5. Both methods give reproducible times, but it is apparent that the same technique must be consistently followed.

Fig. 5.—Effect of changing the order of mixing the reagents.

RANGE OF NORMAL

Abnormal findings cannot be properly evaluated until the range of normal is known. Too few data have been published on normal prothrombin times as

TABLE XIII. REPEATED DETERMINATIONS ON FOUR NORMAL MEN AND WOMEN

CASE	SEX	NUMBER OF DETERMINATIONS	UNDILUTE			DILUTE		
			MEAN	S.D.	(RANGE)	MEAN	(S.D.)	RANGE
1	M	9	17.1	± .3	16.6 to 17.6	77	±7	69 to 101
2	M	11	17.3	± .7	16.1 to 18.6	91	±8	74 to 120
3	F	10	17.0	± .5	15.8 to 17.5	71	±2	67 to 74
4	F	10	17.1	±0.5	16.0 to 17.5	75	±8	66 to 96

measured by the various methods, and care must be taken lest times be reported as "abnormal" when they really come within normal range.

The figures in Table XIII will serve to show the variations possible in this method in a group of healthy individuals. Tests were done on two normal men and two normal women at various intervals over a period of several weeks. The maximum range in the undiluted test was 2.5 seconds and in the 12.5 per cent saline dilution 46 seconds.

In Table XIV are shown the variations in times obtained in a group of ninety-three normal people, fifty-eight women and thirty-five men. Most of these were nurses and medical students between the ages of 20 and 30 years of age. Three different batches of thromboplastin were used. It will be noted that while the standard deviation for the undilute plasma is only 0.6 seconds, the range of normal is three seconds. Dilute times are much less consistent, with a standard deviation of ten seconds and a range of normal from 56 to 115 seconds. Therefore, moderate variations in the dilute times, as obtained by this method, are of doubtful significance. Work now in progress leads us to believe that the practice of diluting the plasma to 12.5 per cent with saline, as is advocated by those using the "dilute method," leads to the introduction of uncontrolled variables and gives inaccurate results. As a matter of fact, the use of saline in making a dilution curve is probably not entirely sound.

TABLE XIV. RANGE OF NORMAL IN HEALTHY INDIVIDUALS
(NINETY-THREE NORMAL INDIVIDUALS)

BATCH OF THROMBOPLASTIN	MEN	WOMEN	TOTAL	UNDILUTE			DILUTE		
				MEAN	(S.D.)	RANGE	MEAN	(S.D.)	RANGE
A	5	12	17	17.2	±.7	15.4 to 18.0	83	±17	61 to 115
B	2	9	11	17.4	±.6	16.9 to 18.3	74	±12	63 to 96
C	51	14	65	17.2	±.6	16.3 to 18.4	74	± 8	56 to 102
Over-all total	58	35	93	17.2	±.6	15.4 to 18.4	76	±10	56 to 115

SUMMARY

1. The prothrombin test as devised by Quick and modified by Brambel has been reviewed in detail and the effect of certain variables examined. These include observations on:

- The stability of thromboplastin in solution and the dry state
- The effect of changing the molarity of the CaCl_2 solution
- The effect of hemolysis and clotting of the blood samples
- The effect of various temperatures on the plasma prothrombin stability
- The effect of changing the order of mixing the reagents

- (f) The effect of meals and time of day on resulting times
- (g) The effect of water bath temperature in running the test

2. The bloods of ninety-three normal persons were tested for prothrombin content. According to the method described, the following values were obtained:

(a) Mean time for undilute plasma was 17.2 seconds with a standard deviation of 0.6 seconds and a range of from 15.4 to 18.4 seconds.

(b) Mean time for 12.5 per cent saline dilution of plasma was 76 seconds with a standard deviation of 10 and a range of 56 to 115 seconds.

3. Repeated tests were made on the same normals and mean standard deviation and range were computed for dilute and undilute specimens.

The authors wish to express their appreciation to Dr. Joseph M. Hayman, Jr., for his many helpful suggestions in the preparation of the manuscript.

A METHOD FOR COUNTING BACTERIA IN THE NASAL CAVITY

APPLICATION OF THE METHOD IN DEMONSTRATING THE ACTION OF INTRANASAL PENICILLIN ADMINISTRATION

THOMAS C. GRUBB AND BRUNO PUETZER
FLUSHING, N. Y.

INTRODUCTION

THE usual method of studying the types of bacteria in the nasal cavity is to insert a sterile cotton swab and culture it in liquid or solid media. Such a procedure is satisfactory for a qualitative examination of the nasal flora, as in the diagnosis of diphtheria or other nasal infections, but is totally inadequate for an estimation of the number of bacteria present.

The reasons for the inadequacy of this method for quantitative purposes become readily apparent from the following points of discussion. It is known (Thomson and Thomson¹), and we have confirmed the fact, that the vestibule of the nostril is colonized with a great number of bacteria, usually air-borne saprophytes, which may contaminate the swab as it is inserted or withdrawn and thus distort the true picture of the types and number of bacteria found within the nasal cavity. The *sine qua non* of making a quantitative estimate of the number of bacteria from a given liquid or surface at repeated intervals for comparative purposes is the use of a precisely uniform sampling method; this appears to be virtually impossible when inserting a swab into the nasal cavity at repeated intervals. Abnormalities in the topography of the nasal cavity often render many areas inaccessible to the swab. It is entirely possible that nasal bacteria are not uniformly distributed over portions of the cavity which are accessible to the swab. Differences in pressure when inserting the swab may also account for variations in the number of bacteria that are recovered on the swab. All of the bacteria removed by the swab may not be dislodged when it is cultured, especially on a solid medium. These few considerations indicate some of the probable causes why the swab method, which we have tested extensively, is unsatisfactory for obtaining a reliable count of the number of bacteria in the nasal cavity.

Recently, Hamburger and co-workers^{2, 3} have devised novel methods for obtaining an estimate of the number of streptococci in the nasal cavity. These consist either of having the subject blow his nose on a sterile cloth which is subsequently cultured in toto and the number of streptococci determined by plate counts of the sample or of pinning a cloth patch to the bed in which the subject sleeps and determining the number of streptococci adhering to the cloth. While both of these methods gave useful information in these workers' experiments, they were admittedly crude and the results were sub-

From the Research Laboratories, Vick Chemical Company.
Received for publication, Feb. 17, 1947.

ject to considerable variation. So far as we are aware, no other method has been published which gives more reliable knowledge of the number of bacteria in the nasal cavity than those previously mentioned.

In determining the efficacy of intranasally instilled antibacterial agents, it is obviously necessary to employ a method of sampling the nasal flora which will give reasonably reliable and consistent results. For this purpose a simple sampling device and procedure have been developed which are believed to give more reliable quantitative results in obtaining a count of the nasal bacteria than any other procedure thus far recorded in the literature. A description of this sampling device, recommended procedure in sampling, and results obtained are reported in this paper.

SAMPLING DEVICE AND PROCEDURE

The construction of the sampling device which can be readily prepared in most laboratories is shown in Fig. 1. It consists of a test tube 13 by 2.5 cm. with the closed end drawn out to a diameter of 0.5 cm. and cut off. This end of the tube is connected to a glass nasal "olive" by a piece of rubber tubing 20 cm. in length. The opening in the nasal olive measures 1 cm. in diameter at the end inserted into the nostril, 2 cm. at the bulge, and 0.5 cm. at the end connected to the rubber tubing. Variations in these dimensions can be made, of course, but we have found this size satisfactory. The open end of the test tube is plugged with cotton, the nasal olive wrapped in paper, and the entire device sterilized in the autoclave.

In using the sampling device, 20 c.c. of sterile broth or Ringer's solution (the latter being preferred since it is less objectionable to most subjects) are pipetted aseptically into the test tube and the cotton plug replaced. The paper is removed from the olive which is inserted tightly into one nostril with one hand while the test tube is held with the other hand. The head is bent slightly forward and the subject slowly raises the tube, as shown in Fig. 2, until he feels the solution just beginning to trickle down into the throat. At this point he lowers the tube which siphons the solution back into the test tube. This process is repeated two times to insure a thorough washing of the nasal cavity.

The nasal washings thus obtained are run through the nasal olive into a sterile, empty, rubber-stoppered 100 c.c. dilution bottle (French square type) which is shaken twenty-five times to disintegrate clumps of organisms. One cubic centimeter of this suspension as well as 1 c.c. of 1:10 and 1:100 dilutions are plated in blood agar to determine the total number of bacteria per cubic centimeter of the nasal washings. Many variations of this sampling procedure suggest themselves, and we have tested the following: (1) Making five successive washings at five-minute intervals with fresh solutions each time and plating each washing individually; (2) making three successive washings and combining the washings before plating; (3) washing both nostrils and combining the washings; and (4) making washings in the morning and afternoon or only once in the same day.

As a result of these preliminary trials, the following procedure was chosen finally as giving the most reliable results for testing the antibacterial action of intranasally instilled agents. In order to determine the average daily normal count for control purposes, at the same time each day for a week or more preceding the use of the agent, a sample is obtained from each subject as follows: The nasal olive is inserted into one nostril and the irrigating solution allowed to flow in and out of the nasal cavity twice; then the olive is inserted into the other nostril and the process repeated. Two additional sampling devices, each filled with 20 c.c. of solution, are used successively in the same way. All three washings (60 c.c.) are then pooled, shaken, and cultured as described previously.

Fig. 1.

Fig. 2.

Fig. 1.—Sampling device for irrigating the nasal cavity.

Fig. 2.—Showing the position of the sampling device for irrigation of the nasal cavity.

During the following week the antibacterial agent is applied in accordance with the requirements of the experiment and nasal washings are carried out at the same time of day as the preceding week. The next week no intranasal applications are made and washings are continued at the usual time.

RESULTS

To illustrate the degree of variation which may be expected when daily counts are made on healthy subjects without the application of an effective intranasal agent, the following protocol is typical of many of our experiments (Table I).

It will be noted that while there are wide daily variations in the counts, within certain limits the subjects tend to remain in high (Subjects C

and E), medium (Subjects A and B), or low (Subject D) count groups. Because of this great variation in normal counts, an intranasally applied antibacterial agent must show a very marked reduction in the counts before its effectiveness can be proven statistically. That such a reduction can be achieved is shown by the results in Table II. when the subjects received nose drops containing 500 units of penicillin per cubic centimeter six times daily at hourly intervals and nasal washings were carried out forty to sixty minutes after the last application of penicillin. The washings from three subjects were seeded with a known concentration of penicillin-susceptible *Staphylococcus aureus* organisms and plated in the usual way. These plates did not show any reduction in counts when compared with the control *Staph. aureus* cultures; hence, it is concluded that a carry over of significant amounts of penicillin into the plates did not occur.

There appears to be no doubt that the application of penicillin nose drops produced a marked reduction in the number of nasal bacteria recovered from healthy subjects. In addition, the repressive effect of penicillin seems to persist for a number of days after use. It is interesting to note that Subject E failed to show as low a total count during the penicillin applications as the other subjects. The fact that most of the organisms cultured during this period from the subject were gram-negative, nonsporulating bacilli probably explains this finding.

DISCUSSION

Since the number of bacteria in the nasal cavity probably fluctuates from day to day, the ideal procedure would be to make a control count in the morning, apply the antibacterial agent throughout the day, and make a second count in the late afternoon or evening. However, when this was tried it was found that the morning irrigation alone produced such a marked reduction in the afternoon counts that it was difficult to interpret the effectiveness of an antibacterial agent tested by this procedure. Hence, it appeared necessary to make nasal counts for a week or more before the experiment to obtain an average normal count; then apply the antibacterial agent and compare the counts obtained. As a further check, counts should be made for a week or longer after use of the antibacterial agent is discontinued; if the counts tend to return to the normal level after a reduction during use of the antibacterial agent, it is a strong indication that the agent has been effective. No experiment should be considered satisfactory unless it can be shown that the antibacterial agent is not carried over in the washings in sufficient concentration to exert a bacteriostatic action in the culture plates.

During the trials with five successive washings it was discovered that the first washing removed very few bacteria, while the successive washings removed increasingly more bacteria until a point was reached where further washings showed a progressively diminishing count. Thus, it is essential that each sample consist of at least three separate washings if the most reliable count is to be obtained.

It is believed that the method described in this report for obtaining a quantitative count of the number of bacteria in the nasal cavity offers a reasonably reliable tool in determining the antibacterial action of intranasal agents. It is obvious also that this method may be used for a qualitative as well as a quantitative study of the nasal flora; that is, a differential count of the various types of bacteria may be made when the blood agar plates are examined. The procedure does not pretend to count all of the bacteria in the nasal cavity, since the irrigating solution obviously does not reach all portions of the cavity, but it appears to produce a representative sample of the flora, by washing out approximately the same area of the cavity on repeated irrigations. Variations in counts may be expected due to leakage around the nasal olive and spilling over into the throat, but in our experience subjects soon learn to avoid these losses after a little practice and the nasal counts become correspondingly more reliable.

Finally, it should be emphasized that the reduction in nasal bacteria of healthy subjects by penicillin reported in this paper does not constitute a direct or implied indication that penicillin is of value in the prevention, treatment, or cure of nasal or other respiratory infections.

SUMMARY

A simple sampling device for washing the nasal cavity with saline or broth is described.

A recommended procedure for using the sampling device to determine the number and types of nasal bacteria is outlined.

The effectiveness of penicillin nose drops in reducing the number of nasal bacteria in healthy subjects, as indicated by the results obtained with the sampling device, is described.

A MODIFIED TECHNIQUE FOR THE DIFFERENTIATION OF PNEUMOCOCCI FROM ALPHA HEMOLYTIC STREPTOCOCCI USING SODIUM DESOXYCHOLATE

ROBERT P. CUTLER, M.D.* AND WILLIAM L. WINTERS, M.D.†
CHICAGO, ILL.

WITH THE TECHNICAL ASSISTANCE OF KATHERINE P. SIMPSON, B.S.

THE differentiation of the pneumococcus from the alpha hemolytic streptococci often is impossible on a purely morphologic basis. At present, the chief means of differentiating these two organisms are the time-honored bile solubility test and the results obtained from typing with Neufeld type-specific sera. Today, this latter method often is time consuming because so many patients have had sulfonamide therapy by the time they enter the hospital. Thus, the suspect pneumococci in sputum often will not type unless passed through one or two mice in order to relieve the organisms of the sulfonamide effects. Therefore, in the large percentage of cases, the bile solubility test has offered the most practical means of differentiation.

Since Neufeld's¹ discovery in 1900 that the pneumococcus was soluble in whole bile, many investigators have described various substances and numerous methods by which this organism may be dissolved. By 1907 the pneumococcus was first distinguished by its bile solubility; it was at this time that Nicolle and Adil-Bey² recognized that bile salts (sodium cholate and sodium choleate) were more effective than whole bile. Though Doehez and Gillespie³ apparently found a true bile-insoluble strain of pneumococcus, according to White and associates⁴ Mair states: "Different strains of pneumococcus show varying sensitiveness to the action of bile, just as they vary in the readiness with which they undergo autolysis in culture; but with a satisfactory technique one is seldom in doubt as to whether a particular strain should be classed as bile soluble or not, and strains which have been kept on culture media for long periods retain the property." A thorough review of the literature pertinent to this subject is given by White and associates.⁴

Liefson's⁵ modification of the bile solubility test proved unsuccessful in our hands. The purpose of this paper is to present what we believe to be a faster and simpler test, which has proved to be accurate. This test, requiring little equipment, is suitable for the laboratory of the intern or for the general hospital.

METHOD

Equipment.—The equipment, as illustrated in Fig. 1, includes the following:

1. Fresh solution of 10 per cent sodium desoxycholate, pH 7.4.
2. Platinum wire loop.

From The Robert Bruce Preble Laboratory, Cook County Hospital, under the direction of the Department of Medicine, Northwestern University Medical School.

Received for publication, March 28, 1947.

*Robert Bruce Preble Research Fellow, 1944-1945, Cook County Hospital.

†Attending Physician, Cook County Hospital.

3. Microscope with oil immersion lens and immersion oil.
4. Bunsen burner.
5. Two glass microscope slides.
6. Distilled water.
7. Gram stain equipment.

Technique.—The test, to be done at a temperature not above 50° C., consists of the following steps:

1. To four drops of fresh 10 per cent sodium desoxycholate on the first glass slide (*I*) add two medium-sized loopful of the material containing the organism to be tested (washed sputum, broth suspension of the organism, or colonies from agar plate). Allow the slide to stand for ten minutes and shake gently occasionally.

2. On one-half of the second glass slide (*II*) make a direct smear from the original material as a control (*C*).

3. After ten minutes, to one drop of distilled water on the other half of the second glass slide (*II*), add one loopful of material from the mixture of the first glass slide as the test (*T*).

4. Dry this second glass slide (preferably on a warm ring stand), Gram stain, and compare the control smear with the test smear under oil immersion. The absence on the test smear of gram-positive encapsulated organisms, such as are present on the control smear, indicates a positive test. The presence of such organisms on both test and control smears indicates a negative test; in other words, the organisms tested are not pneumococci.

Fig. 1.—Diagram of procedure.

RESULTS

This method was used in testing six different types of pneumococci previously identified by serologic typing and one strain of gamma nonhemolytic streptococcus. In Fig. 2 the results obtained by our method are compared with those obtained by Liefson's method in fifteen cases. In one of these cases there

was only partial solution of the pneumococci with our method. Using Liefson's technique we found complete solubility in one case and no appreciable solubility in the others.

As a means of checking our technique, we compared its results with those obtained by the standard macroscopic method described by Kolmer and Boerner⁶ in a series of twenty-five different types of pneumococci in pure culture. Complete solubility occurred by both methods in all the types tested.

Repeated success with our method during the year in a series of over 200 cases, and covering more than 500 separate tests, constitutes further indication of its accuracy. In no instance in seventy-seven cases of known streptococcal infections tested have we ever dissolved the alpha, beta, or gamma streptococci by this method.

Fig. 2.— - - - - Liefson's method. — Slide method. O, "Quellung shadows" observed with the addition of type-specific serum. ●, "Quellung shadows" and also ordinary "Quellung phenomenon" observed with the addition of type-specific serum. G. S., Gamma streptococcus; roman numerals refer to pneumococcus types.

In the course of this work the observation was made that if the test (*T*) was not allowed to dry, but instead type-specific serum was added directly to the moist preparation, the presence of enlarged capsules or "Quellung shadows" were noted eight times in Liefson's test and three times in our test in the representative series (Fig. 2). The bodies of the organisms were apparently dissolved by the bile salt and the capsules remained intact. The intact capsules were invisible until type-specific serum was used and the test was examined under oil immersion with a dull light; the capsules appeared translucent and took no stain, whereas the body, or normally staining portion, was absent.

COMMENT

In a study of twenty-seven pneumococcal infections, 77 streptococcal infections, and 11 miscellaneous infections, the slide test described in this report served as an accurate method of identifying pneumococci in spinal fluid, washed sputum, and in either pure or mixed cultures grown on blood or proteose agar media. In the latter instance, when the contaminating organisms were alpha

hemolytic streptococci, we found that the addition of the six groups of Neufeld typing sera served to identify the pneumococci by "Quellung shadows" and the alpha hemolytic streptococci as undissolved intact organisms.

The presence of the "Quellung shadows" suggests that proteolysis occurs in the presence of excess sodium desoxycholate. Goebel and Avery⁷ have shown that autolysis is accompanied by proteolysis and lipolysis, whereas sodium desoxycholate, in excess, inhibits the action of pneumococcal protease, but not lipase. These authors, however, found that pneumococcus is dissolved in the presence of an excess of the bile salt and concluded that bile solubility is probably not identical with autolysis. We also found that the body of the organism is dissolved even though the protease is apparently inhibited in the presence of excess sodium desoxycholate. Further, we found an apparent resistance at times of the carbohydrate or capsular portion of the pneumococcus to the action of excess sodium desoxycholate as was clearly shown by the "Quellung shadow" phenomenon.

SUMMARY

1. A simple modification of the bile solubility test is described.
2. The presence of the "Quellung shadows" in bile-tested material from mixed cultures is suggested as a further aid in the differentiation between pneumococci and alpha hemolytic streptococci.
3. The significance of the "Quellung shadows" is discussed.

A SIMPLE APPARATUS FOR CULTURING NEISSERIA GONORRHEA UNDER PARTIAL CARBON DIOXIDE TENSION

CLARENCE W. NICHOLS, JR.
BERKELEY, CALIF.

AN EVER-INCREASING demand for the isolation and identification of *Neisseria gonorrhea* by culture methods, not only as an aid to diagnosis, but also as a criterion for cure of both male and female patients following chemotherapy, makes it desirable that a simple apparatus for culturing gonococci be made available.*

The following simple apparatus has been devised to meet this demand and has proved to be readily applicable for routine gonococcus culture methods.

The apparatus consists of a standard laboratory desiccator (Scheibler type, 150 mm.), having an approximate capacity of 2,500 c.c. and a plexiglass Petri dish holder, so constructed to accommodate either a medicine dosage glass or a porcelain crucible as a reaction vessel for the production of carbon dioxide by the action of dilute HCl with sodium bicarbonate.

The Petri dish holder (Fig. 1) is constructed from the ordinary plastic, plexiglass ($\frac{1}{4}$ inch thickness), and the component parts of the holder (top, base, and three supports) are cemented together with an adhesive made by dissolving plastic shavings in acetone. Increased rigidity of the culture plate holder is accomplished by dovetailing the supports at the top and base. Since the culture plate holder fits snugly in the desiccator, a series of holes (0.4 cm.) are drilled in the top and base plates to insure adequate circulation of CO_2 throughout the desiccator. Sufficient CO_2 tension is produced by the addition of 3 or 4 c.c. of 10 per cent HCl to approximately 1 Gm. of sodium bicarbonate.

The following procedure is employed in preparing the apparatus for incubation. After the culture plates have been inoculated, they are placed in the culture plate holder, which is then introduced into the desiccator. The reaction vessel containing the sodium bicarbonate (Fig. 2, A) is placed in the round opening on the top plate of the culture dish holder. The lid of the desiccator is tightly sealed in place, leaving the stopcock open. Dilute HCl is then delivered with a 5 c.c. diluting pipette through the open stopcock into the reacting vessel. The stopcock is immediately closed and the entire apparatus is placed in a bacteriologic incubator for the desired length of incubation at 37° centigrade.

The advantages of an all-glass culture apparatus, plus the noncorrosive plexiglass culture plate holder, are obvious when one remembers the disagreeable features of using a copper Petri dish holder utilizing a burning candle for the production of carbon dioxide. The previously described apparatus can easily be cleaned and sterilized after each incubation period. If additional moisture is

Received for publication, March 14, 1947.

*The apparatus was devised and used by the author while serving as technical sergeant, Medical Department, in the Armed Forces of the United States.

Fig. 1.—Plexiglass Petri dish holder, with a 3.5 cm. hole in the top plate to accommodate either a medicine dosage glass or porcelain crucible as a reaction vessel for the production of carbon dioxide.

necessary to safeguard against dehydration of the culture media during incubation, a very small amount of water can be placed on the floor of the desiccator before the culture plate holder is introduced into the desiccator.

The apparatus has been used by the author for more than one year and found satisfactory for routine gonococci cultures, using either chocolate-agar (Difco) or Peizer media.

SUMMARY

A simple apparatus for culturing *Neisseria gonorrhoea* under partial carbon dioxide tension is described. It has been found to be adequate for the culture of gonococci as an aid to diagnosis.

A TEST FLUID FOR CONTROL OF THE GOLD REACTION

CARL LANGE, M.D.

ALBANY, N. Y.

CORRECT results in the colloidal gold test depend primarily upon two physicochemical factors¹: the first is the pH of the milieu,² which is optimal at 7.4, and the second is the sensitivity (dispersity) of the gold sol, which should be controlled by use of a photoelectric colorimeter.³ A test fluid is required as an additional safeguard to demonstrate that optimal conditions have been secured.

Such a test fluid may be prepared by pooling approximately equal amounts of twenty or more normal sera. Specimens that are chylous or otherwise abnormal in appearance, or that react in the complement-fixation test for syphilis, are excluded. Additional criteria for the "normality" of the sera are not used. Exactly 5 ml. of the pooled sera are diluted with phosphate buffer, pH 7.4,⁴ in a 250 ml. volumetric flask. Fifty milliliters of this solution are diluted with 50 ml. of glycerol, the final dilution being 1:100. The fluid is kept in the refrigerator and is freshly prepared each month. One-tenth milliliter is tested in duplicate every working day in the same manner as a specimen of cerebrospinal fluid.

The test fluid when satisfactory yields a uniformly standard curve characterized by three factors: (1) The degree of coagulation, determined by the gold color standard, is 6 in the first or 1:15 dilution; (2) the maximum reaction, 15, occurs in dilution 1:114; and (3) the sum of the ten numerical color values is between 95 and 100. The exact reproducibility of the test fluid was demonstrated by testing ten different serum pools at one time with the same reagents. The results were identical with reference to the three factors mentioned. The negligible deviations in other dilutions, particularly in the postzone, are not due to differences of the test fluid but to inevitable slight inaccuracies of pipetting. To obtain such results, the dilution of the serum pool (1:100) must be exact. Experience has shown that on rare occasions an abnormal serum that has been inadvertently included may spoil a pool.

The standard curve is the final criterion of the suitability of the test fluid and other reagents and particularly of the gold color standard. In fact, it provides a rigorous control of the test as a whole. Deviations from the standard curve indicate that a reagent is unsatisfactory. The source of the deviation is determined by replacing one reagent at a time, which can be done easily if a set of reagents known to be satisfactory is available. For example, if a new buffer is substituted and the test fluid does not give the standard curve, the new buffer solution is evidently at fault.

Use of the test fluid is illustrated in Table I. In the first four items, in which the colloidal gold solutions are of satisfactory sensitivity as indicated by the turbidimetric value, the pH of the milieu is 7.4 by potentiometric determination and the buffer is of satisfactory pH and molar concentration. The

*Citrate gold 1:10,000³ was used.†The routine phosphate buffer pH 7.4 was used except in the case of Nos. 1, 6, and 7 in which phthalate buffer pH 5.2, pH 6.0, and pH 6.4, respectively, were used.
‡The Δ indicates the location of the maximum reaction in prezone curves.

findings obtained are almost identical, although the gold sols were prepared on different days and different test fluids were used. When the pH of the milieu is more acid than 7.4, the results vary markedly from those obtained when the pH is maintained at 7.4, as in items 5, 6, and 7. When the molar concentration of the buffer is incorrect (item 8), the results again show clearly that a mistake has been made. The pH and the molar concentration are controlled simultaneously by the test fluid, which is not possible by potentiometric determination.

In items 9 and 10, citrate gold sols 1:10,000 prepared with impure distilled water were used. The turbidity and sensitivity of these sols were abnormally low. Below a certain limit, abnormality is clearly demonstrable by the test fluid. In both Nos. 9 and 10, the degree of coagulation in the prezone is abnormal; in No. 10, even the location of the maximum is shifted and the sum total is markedly decreased.

Two controls for particle size and reproducibility of the test as a whole (turbidimetric determinations and use of a test fluid) are recommended. A gold sol having an abnormal particle size can be detected by turbidimetry. Such findings indicate the use of impure distilled water. The test fluid, however, shows in detail the type and degree of deviation from the standard reaction.

OTHER TEST FLUIDS

Before pools of normal sera were found to provide a satisfactory test fluid, the value of other types of fluid was studied as follows:

1. Four cerebrospinal fluids of different protein patterns (types A, B, C, and D), preserved by adding equal amounts of glycerol, were used. If the pH and the sensitivity were correctly adjusted, reproducible results were obtained. It was difficult, however, to obtain four suitable fluids for the purpose, and when a satisfactory specimen was obtained, only a small amount was available.

2. Use of cerebrospinal fluids from patients with paresis⁶ is unsatisfactory. Only test fluids yielding a prezone curve, such as types B or C,* can demonstrate that a false D (paretic) curve² has been obtained if the pH is too acid.

3. Purified globulin fractions yield either plateau (D) or prezone (B or C) curves. Even if the pH of the milieu is maintained at 7.4, test fluids giving a plateau (paretic or type D) curve are inadequate. A solution of 20 mg. per 100 ml. of gamma globulin was found to yield the same plateau or first-zone curve as a specimen of cerebrospinal fluid from a paretic. A plateau of complete coagulation was obtained with both, up to a final dilution of 1:320. A solution of 10 mg. per 100 ml. of globulin gave a plateau of complete coagulation in a 1:160 dilution. A solution of 15 mg. per 100 ml., however, could not be differentiated by end-point titration from a solution of either 10 or 20 mg. per 100 ml. Hence, test fluids that yield a plateau curve, besides being inadequate as a control of the pH, provide only a rough control in the quantitative adjustment or sensitivity.

*Classification of curves obtained in the colloidal gold test: A. Obtained with normal cerebrospinal fluid; B, formerly designated as second zone or syphilitic; C, formerly designated as hemato-genous, third zone, or meningitic; D, formerly designated as paretic or first-zone curve.

4. Edestin,⁷ widely used as a test fluid, yields a first-zone curve and in some respects is even inferior to gamma globulin.

5. Pseudoglobulin obtained from normal horse serum by repeated fractionation, between 33 and 45 per cent saturation with ammonium sulfate, produces a prezone curve. It provides a highly satisfactory control on quantitative and qualitative reproducibility of the gold reaction. Its preparation is somewhat complicated, however, and the reproducibility of the test fluid itself is unsatisfactory.

SUMMARY

A test fluid prepared from pools of normal sera for use as a control in the colloidal gold test is described. The fluid is simple to prepare and reproducible. The procedure recommended permits identical results to be obtained in different laboratories and is a step forward in standardization of the gold reaction.

Hal Downey, Ph.D.

PROFESSOR OF HISTOLOGY AND HEMATOLOGY, 1917-1946
UNIVERSITY OF MINNESOTA, EMERITUS PROFESSOR, 1946—

IN HONOR OF DR. HAL DOWNEY

MY FRIEND, Professor Hal Downey, retired last June from active duty on the teaching faculty of the University of Minnesota. This event prompted former students and associates to dedicate this issue of the JOURNAL OF LABORATORY AND CLINICAL MEDICINE to him as a mark of esteem and gratitude. They asked me to join them in this token of respect.

I am one of the few survivors of the old school of nonclinical hematology and had the privilege of working with Dr. Downey when he visited Europe in 1911, with the intention of extending his earlier studies on the blood-forming organs of the lower vertebrates (*Polyodon* in particular) to mammals and man. He went first to Pappenheim in Berlin. But Pappenheim's more philosophical mind and mode of viewing morphological problems were not entirely to Downey's taste. So he left Berlin and went to Strassburg to work in my laboratory. The equipment there was very poor and no technical assistance was available. We had only the simplest microscopical techniques with which to tackle the problem of the origin of the lymphocytes—which was our goal.

When Downey left me, I gave up hematology and never returned to it. Downey, however, remained faithful to the subject. Acknowledging that the clue to the lymphocyte problem, the relation between lymphoblasts and myeloblasts, is only approachable through experiment—that is, changing the normal environment of the cells—he decided to study the blood cells under their pathological conditions.

I do not feel qualified to praise Dr. Downey's achievement in the field of clinical hematology and must leave this to more competent persons. But I am very proud of having served Dr. Downey as a guide at the beginning of a career in which he has become one of the foremost hematologists of our age.

AN EVALUATION OF ALTERATIONS PRODUCED IN LYMPHOID TISSUE BY PITUITARY-ADRENAL CORTICAL SECRETION

THOMAS F. DOUGHERTY AND ABRAHAM WHITE
NEW HAVEN, CONN.

THE involvement of lymphoid tissue and of lymphocytes in numerous normal and pathologic processes is well recognized by pathologists and experimental investigators. However, the relation of the experimental and pathologic findings to the actual function of the lymphocyte has remained obscure. The normal physiologic control and function of this ubiquitous tissue has been largely speculative. Perla and Marmorston,¹ in discussing lymphoid tissue, ask the following questions: "Why does the mammal possess so large and diffuse an organ (lymphoid tissue)? What is the purpose of this mass of lymphoid tissue? Why are such large numbers of lymphocytes poured into the circulation daily, without causing a fluctuation in the lymphocytic count of the blood? Where do the lymphocytes go? What is the function of the lymphocyte?"

Drinker and Yoffey² have stated that the only definitely known function of lymphoid tissue is the production of lymphocytes. Actually, the origin of the lymphocyte is still a matter of controversy among some histologists. The multipotentiality of the lymphocyte has been demonstrated.³ Lymphocytes may be sources of immature cells, which transform to specialized cellular forms when the necessity arises, or a reservoir of potential macrophages. However, these roles are potentialities of the lymphocyte; the normal functions of the cell morphologically identified as a lymphocyte have not been elucidated.

The constancy in the size of the lymphoid tissue and in the numbers of circulating lymphocytes suggest the possibility that the rate of growth of lymphocytes and their entry into the circulation may be under endocrine control. It is not unlikely that these processes may be intimately related also to factors concerned with the peripheral disposition of lymphocytes. Addison noted an increase in lymphoid tissue in his original description of the disease which bears his name (quoted by Grollman⁴). Conversely, numerous investigators have found that the secretions of the adrenal cortex have a regulatory effect on the size of the thymus.⁶⁻¹² This paper includes some of the data obtained in studies initiated to investigate the hypothesis that pituitary adrenotrophic hormone (adrenotrophin), by its action on the adrenal cortex, influences the size, structure, and function of lymphoid tissue.

EXPERIMENTAL OBSERVATIONS

Pituitary-Adrenal Cortical Control of Lymphoid Tissue Weight.—The daily subcutaneous injection of 1 mg. of adrenotrophin¹³ in 0.5 c.c. aqueous solution

From the Departments of Anatomy and Physiological Chemistry, Yale University.
The data reported in this paper have been obtained in studies aided by grants from the Josiah Macy, Jr., Foundation and the Fluid Research Fund of Yale University School of Medicine.

into normal CBA mice, 60 to 80 days old, resulted in a significant decrease in the weight of lymphoid tissue. This decrease was observed as early as fifteen hours following injection and persisted throughout the fifteen-day period during which the mice were treated¹⁴ (Figs. 1 and 2). The thymus remained smaller than other lymphoid structures during the period of study. Although the spleen actually increased in weight during the fifteen days of hormone administration, this increase was due to the accumulation of large numbers of degenerating lymphocytes and to an extensive edema. The Malpighian corpuscles were markedly decreased in size. The histologic changes in these tissues will be discussed later. Adrenotrophin has now been reported to produce similar weight changes in lymphoid organs of the rat.¹⁵

Adrenalectomized mice maintained for eight days by daily, subcutaneous injections of 0.025 mg. desoxycorticosterone acetate in oil (Schering), showed marked hyperplasia of all the lymphoid organs studied (Figs. 1 and 2). The alterations in lymphoid tissue following adrenalectomy were not influenced by desoxycorticosterone acetate since the maintenance dose of this steroid produced no effect on the weight or histology of lymphoid tissue in normal or adrenalectomized mice.^{16, 17}

Pituitary Control of Adrenal Size and Cholesterol Content.—Repeated daily injections of adrenotrophic hormone resulted in the expected increase in weight of the adrenals (Fig. 2). The cholesterol content of the adrenals of hormone-treated mice varied during the fifteen-day period, depending on the particular day the glands were obtained. Whereas a single injection of hormone produces an acute decrease in adrenal cholesterol within a few hours after administration¹⁸ (Fig. 3), repeated daily injections increase the adrenal cholesterol to values above normal.¹⁹

Pituitary-Adrenal Cortical Control of the Numbers of Circulating Lymphocytes.—In the fifteen-day experiments previously described animals were sacrificed in groups at intervals of three days. All of these mice were killed approximately twenty-four hours after the last injection of adrenotrophic hormone. In addition to weighing the tissues, red and white blood cell counts and differential counts were made. Total hemoglobin and whole blood specific gravity were also determined. The data are summarized in Table I. The number of circulating lymphocytes in the adrenotrophic hormone-treated mice was significantly lower throughout the fifteen-day period.²⁰

Similar studies have been conducted on adrenalectomized mice maintained on daily injections of 0.025 mg. desoxycorticosterone acetate over an eight-day period and on adrenalectomized rats given 0.7 per cent sodium chloride and 0.3 per cent sodium bicarbonate as drinking fluid. These data are presented in Tables I and II. In adrenalectomized mice and rats the number of lymphocytes increased significantly.²⁰ In the rats there was a significant lymphocytosis at six days following adrenalectomy, whereas mice had a lymphocytosis twenty-four hours after operation. Furthermore, the specific gravity of the whole blood of adrenalectomized mice maintained with desoxycorticosterone did not indicate a hemoconcentration sufficient to account for the increased number of lymphocytes (Table I). The number of circulating lymphocytes in adrenalectomized

EFFECT OF ADRENOTROPIC HORMONE INJECTION AND ADRENALECTOMY ON TISSUE WEIGHTS OF THE MOUSE

Fig. 1.—The columns represent weights of paired lymph nodes, adrenals, and testes of mice, 60 to 80 days old, of the CBA strain (Strong). The control group represents thirty mice, and there were twenty-five mice in each of the experimental series. The adrenotropic hormone-injected mice were treated daily with 1.0 mg. of hormone for fifteen days; the adrenalectomized mice were sacrificed one week after adrenalectomy.

Fig. 3.

Fig. 4.—Alterations produced in total leucocyte, lymphocyte, and polymorphonuclear cells in blood of normal mice receiving at zero time a single subcutaneous injection of 1.0 mg. of pituitary adrenotropic hormone. The averages at each successive time interval are for groups of 99, 3, 3, 7, 7, 7, 6, 7, and 7 animals.

Fig. 5—Alterations produced in total leucocyte, lymphocyte, and polymorphonuclear cells in blood counts of normal rats receiving at zero time 50 mg. of adrenotropic hormone subcutaneously. The averages at each successive time interval are for groups of 42, 12, 12, 8, and 12 animals

Fig. 6—Alterations produced in total leucocyte, lymphocyte, and polymorphonuclear cells in blood counts of normal rabbits receiving at zero time 100 mg. of adrenotropic hormone subcutaneously. The averages at each successive time interval are for groups of 18, 4, 4, 4, 2, and 3 animals.

rats provides further evidence that the increase in lymphocyte counts in the operated mice is not due to hemoconcentration, since the adrenalectomized rats had an approximately normal blood volume and yet showed a lymphocytosis (Table II).

Significance of Lymphocyte Counts as an Index of Adrenal Cortical Activity.—The slight, but significant, lymphopenia in mice twenty-four hours after the previous injection of adrenotrophin suggested that the numbers of circulating lymphocytes might be an index of the level of adrenal cortical activity. On the basis of the adrenal cholesterol analyses shown in Fig. 3, maximum adrenal cortical activity occurred at six hours following a single injection of adrenotrophic hormone. Therefore, the blood of mice, rats, rabbits, and dogs was studied at intervals shortly following subcutaneous injection of this hormone.

Fig. 7.—Alterations produced in the leucocytes of adrenalectomized mice receiving at zero time 1.0 mg. of adrenotropic hormone subcutaneously. The lower chart for normal animals is reproduced for comparison. The averages represent sixty control animals at zero time and five at each successive interval.

A single subcutaneous injection of 1.0 mg. of adrenotrophin in mice produced a precipitous decline in the numbers of circulating lymphocytes which was evident within one hour and reached its lowest point within nine hours¹⁸ (Fig. 4). Following this time, the numbers of blood lymphocytes rapidly increased and at twenty-four hours after hormone administration had returned

almost to normal. The lymphopenic response also was observed in rats injected with 5 mg. of adrenotrophic hormone (Fig. 5) and in dogs given 10 mg. of the hormone. In rabbits receiving 10 mg. of adrenotrophin the numbers of lymphocytes again decreased very rapidly, reaching their lowest value within three hours, and did not return to normal levels as rapidly as in the other species (Fig. 6).

The lymphopenic response produced by adrenotrophic hormone is dependent upon the mediation of the adrenal cortex. The hormone has no effect on blood lymphocytes in adrenalectomized animals (Fig. 7). Further, the specific hormonal action of adrenotrophin is seen from the fact that two other pure proteins, prolactin²¹ and serum gamma globulin (human), had no effect on blood lymphocyte levels.

Fig. 8.—Effect of subcutaneous injection of 0.5 c.c. aqueous adrenal cortical extract on the leucocyte counts of normal and adrenalectomized mice. There are eight animals at each interval in the unoperated series and six animals at each interval in the adrenalectomized group.

Lymphopenic Response Produced by Various Adrenal Cortical Preparations.—The role of the adrenal cortex as a mediator in the lymphopenic effect of adrenotrophic hormone led to a study of various adrenal cortical hormone preparations. It was of considerable interest to determine which adrenal cortical steroids might be primarily responsible for the lymphopenia. Single injections of aqueous adrenal cortical extract (Wilson) or of adrenal cortical steroids in oil (Upjohn) produced lymphopenic responses in normal and adrenalectomized mice and rats¹⁸ (Fig. 8 and Table III). These same adrenal cortical preparations were also effective in rabbits and in man. Corticosterone

and compound E (Kendall) produced lymphopenia in adrenalectomized mice (Table III). On the other hand, desoxycorticosterone acetate, in the doses used, did not produce lymphopenia in either normal or adrenalectomized mice (Table III). This lymphopenic effect of adrenotropin and of certain adrenal cortical preparations has now been confirmed by other investigators in rats,^{22, 23} dogs,²⁴ and human beings.^{25, 26}

TABLE III. AVERAGE ALTERATIONS IN BLOOD CONSTITUENTS FOLLOWING SINGLE, SUBCUTANEOUS INJECTIONS OF ADRENAL CORTICAL STEROIDS IN NORMAL AND IN ADRENALECTOMIZED MICE

Pituitary-Adrenal Cortical Mediation of the Lymphopenia Induced by Stresses.—A wide variety of physical, chemical, and physiologic stresses have long been known to produce a lymphopenic effect. The literature pertaining to this subject will be discussed subsequently. It was considered possible that some of these stresses might cause a lymphopenia as a result of pituitary-adrenal cortical stimulation. Data have been obtained confirming this hypothesis. The following types of stresses have been studied: a single injection of arsenite, benzene, histamine, pitressin, or typhoid vaccine; exposure to cold; and inanition. When exposed to any of these stresses, normal mice or rats re-

sponded with a lymphopenia, whereas adrenalectomized mice or rats showed no decrease in lymphocyte counts. Moreover, neither pitressin nor benzene induced lymphopenia in hypophysectomized rats. Some of these findings are shown in Figs. 9 and 10.

Alterations Seen in Numbers of Polymorphonuclear Leucocytes.—The term polymorphonuclear leucocyte is used here as a matter of convenience. The segmented forms should probably be referred to as heterophils in the mouse and the rat and as pseudoeosinophils in the rabbit. Other polymorphonuclear forms such as the basophil and the eosinophil are not grouped separately since they were few in number.

Fig. 9.—Effect of subcutaneous injection of 125 mg. benzene on the leucocyte counts of normal and hypophysectomized rats. Averages represent four animals at each interval in the hypophysectomized series and six animals in the normal series.

A slight but definite increase in the number of polymorphonuclear leucocytes was found in the mice given repeated injections of adrenotrophic hormone. It is questionable whether this increase was specifically related to the injection of the hormone, since a single injection of many agents, including adrenotrophin, produces an increase in circulating polymorphonuclear leucocytes when administered to either normal, adrenalectomized, or hypophysectomized animals (Figs. 7 to 10). The number of polymorphonuclear cells was lower, but not signifi-

cantly so, in the adrenalectomized mice. These cells were, however, increased in number in the adrenalectomized rats. In view of the fact that the polymorphonuclears did not increase in the blood of adrenalectomized mice, in spite of the hemoconcentration, it would seem that there was an actual suppression in the production or delivery of polymorphonuclears. A possible role of the adrenal cortex in the regulation of blood polymorphonuclear cells is suggested also by the work of Corey and Britton²⁷ who found a markedly decreased number of these cells in adrenalectomized cats. Pertinent discussion of this point has been presented previously.¹⁸

Fig. 10.—Alterations in numbers of leucocytes of adrenalectomized and normal mice following the subcutaneous injection of 2.0 units of pitressin. The control values are averages of ninety-nine mice in the unoperated group and forty-two in the adrenalectomized series. The values at each successive time interval were obtained on groups of six animals.

Pituitary-Adrenal Cortical Control of the Numbers of Circulating Erythrocytes.—Repeated injections of adrenotrophic hormone into normal mice resulted in a slight, but significant, polycythemia.²⁰ On the other hand, adrenalectomized mice, showing some degree of hemoconcentration despite daily injections of desoxycorticosterone acetate, had normal numbers of erythrocytes. Further, the significant decrease of red cells in adrenalectomized rats maintained with a normal whole blood specific gravity is additional evidence that pituitary-

adrenal cortical secretion exerts an influence over the numbers of circulating erythrocytes. The values for hemoglobin concentrations support these conclusions (Tables I and II).

In mice and rats given single injections of adrenotrophin, an initial increase in both hemoglobin concentration and red cell count was observed three hours after injection.¹⁵ Thereafter, these constituents of the blood gradually declined, and twenty-four hours after hormone injection the red cells and hemoglobin concentrations were distinctly lower than normal. The specific gravity of the whole blood was not significantly altered during the twenty-four-hour period of study, although at the twenty-fourth hour there was evidence of a slight hemodilution.

Adrenal cortical preparations which produced a lymphopenia increased red cell counts and hemoglobin concentrations in a manner similar to that described for adrenotrophic hormone.

Histologic Changes in Lymphoid Tissue Produced by Adrenal Cortical Secretion.—The marked lymphopenia observed shortly following the injection of adrenotrophic or adrenal cortical hormones, or following a variety of stresses known to augment pituitary-adrenal cortical secretion, raised the problem of the mechanism inducing this lymphopenia. Several possibilities suggested themselves: failure of delivery of lymphocytes to the circulation, failure of lymphocyte production, or increased rate of peripheral removal of lymphocytes. The basis for the lymphopenia was sought in a detailed study of the lymphoid tissues following hormone administration.

In all the lymphoid tissues studied, that is, thymus, lymph nodes, spleen, and Peyer's patches, a single injection of adrenotrophic or of adrenal cortical hormones resulted in early dissolution of medium-sized and small lymphocytes within the lymphoid tissues. The dissolution of lymphocytes was accompanied by a marked edema. The term dissolution of lymphocytes has been used in the sense of a disintegration characterized by karyorrhexis pycnosis, or by a shedding of the cytoplasm of the cell.^{16, 17} Downey and Weidenreich²³ have shown that under normal conditions lymphocytes may bud off portions of their cytoplasm. All of these alterations may be seen in the lymphoid tissues at the time of dissolution of lymphocytes. Certainly, the pycnosis and the disintegration of the nuclei of the lymphocytes result in death of these cells. However, many of the cells have markedly shrunken nuclei which have lost their normal chromatin distribution and have assumed various bizarre shapes. Although the cytoplasm of many of these cells has been lost, it is not to be construed that these cells are necessarily nonliving. It is possible that cells of this type might regenerate cytoplasm and again become normal lymphocytes.

In addition to the alterations in individual lymphocytes, there was an increased development of immature plasma cells similar to the cells described by Rohrer²⁴ or the "acute splenic tumor cell" of Rich, Lewis, and Wintrobe.²⁵ Investigations in our laboratory have demonstrated²¹ that the increase in these cells occurs within the first few hours following hormone injection in rabbits. It has also been observed that not only is there an increased number of so-called

immature plasma cells, but that many smaller lymphocytes may develop basophilic cytoplasm, thus giving to these cells the superficial appearance of plasma cells.

The dissolution of lymphocytes is maximal between one and six hours after hormone injection in both mice and rabbits. This is then followed by a removal of cellular debris by macrophages. These macrophages are numerous in all of the lymphoid organs studied and contained large amounts of nuclear debris. Concomitant with the dissolution of lymphocytes, early alterations in fixed reticulum cells are evident. These changes consist in an increase in the amount and structure of cytoplasm of the histiocytes. Although these cells were derived from fixed reticulum cells, they are not highly active in removal of the vast amount of nuclear debris.

Within six to nine hours after administration of either adrenotropic or adrenal cortical hormones, most of the nuclear fragments scattered about in the lymphoid tissues had been phagocytized, and the tissues in most of the animals at this time showed little evidence of further lymphocyte dissolution. During this period and subsequently the edema subsided and there was evident a beginning return to normal lymphoid structure. The period of recovery was characterized by differentiation of lymphocytes from reticulum cells and resumption of mitosis in lymphocytes. Within twenty-four hours after hormone injection, the lymphoid structures, with the exception of the thymus, contained normal numbers of lymphocytes. These described changes in lymphoid structures as a result of increased concentration of circulating adrenal cortical hormone have been confirmed by Yoffey.²³

The high degree of specificity of the acute action of adrenal cortical steroids on the lymphocytes of animals is seen from the fact that bone marrow elements other than lymphocytes showed no evidence of degeneration. *Thus, lymphocytes represent an important site of action of certain adrenal cortical steroids.*

Examination of other tissues such as the lung showed that the lymphopenia was not due to an accumulation of the lymphocytes in any of the large capillary beds. None of the other tissues examined were edematous.

Adrenotropic hormone injected into adrenalectomized mice had no effect on lymphoid tissue. Adrenal cortical extracts (aqueous or oil), corticosterone, or compound E when injected into adrenalectomized mice produced histologic alterations indistinguishable from those seen after administration of these preparations to normal animals. On the other hand, desoxycorticosterone acetate injection into normal or adrenalectomized mice had no effect on lymphoid tissue structure in the doses employed (0.025 to 2.5 mg.). Recently, it has been reported²² that large doses of desoxycorticosterone acetate produced an atrophy of the thymus, but not of other lymphoid structures, in adrenalectomized rats.

A more detailed description of the histologic alterations resulting from increased concentrations of circulating adrenal cortical steroids has been published.¹⁷ Any one of the nonspecific stimuli studied, and mentioned previously in connection with alterations in numbers of blood lymphocytes, induced alterations in lymphoid tissue in normal mice similar to those described for adreno-

trophic hormone or for the effective adrenal cortical preparations. However, these same stimuli, in the degree employed, had no effect on the lymphoid tissue of adrenalectomized mice.

Adrenal Cortical Control of Release of Blood Globulin From Lymphocytes.—The dissolution of lymphocytes observed following injection of adrenotrophic or adrenal cortical hormones suggested that a portion of the released cytoplasmic nitrogen could enter the metabolic pool and participate in physiologic processes involving nitrogen. A portion of the nitrogen released by lymphocyte dissolution was sought in the serum proteins. Since lymphoid tissue has been suggested as a site of antibody production (for a review of the literature see Perla and Marmorston¹), examination of the globulin fraction of the serum was of particular interest.

The daily injection of 1 mg. of adrenotrophic hormone into normal mice for fifteen days produced a statistically significant increase in the total serum proteins. On the other hand, adrenalectomy in the mouse was followed by a significant decrease in the level of total serum proteins. This decrease was even more significant when considered in the light of the slight degree of hemoconcentration which occurred in the adrenalectomized mice despite the daily administration of small amounts of desoxycorticosterone acetate. A single injection of 3.0 mg. of adrenotrophin into rats resulted in a significant increase in the total serum proteins at three-hour and six-hour periods after hormone injection at which the sera were studied. At twenty-four hours after hormone, the level of serum proteins had returned to normal values.^{16, 33, 34}

The injection of either adrenotrophic hormone or adrenal cortical steroids into normal rabbits produced a significant increase in the total globulin content of the serum during the three to twenty-four hour period that the animals were studied. Electrophoretic patterns revealed that the increase in globulin was a result of rises in both the beta and gamma globulin components of the rabbits' sera.^{33, 34} The albumin and the alpha globulin fractions were unaltered. These data assume added significance in the light of the demonstration that washed lymphocytes from the lymphoid tissue of normal rabbits contain a protein which has an electrophoretic mobility identical with that of the normal gamma globulin of rabbits' blood.^{33, 34} Kass,³⁵ working with human lymphoid tissue, has confirmed the presence in lymphocytes of a protein immunologically identical with normal serum gamma globulin.

A second component of lymphocyte extracts is probably identical with the beta globulin of rabbits' blood. It is, therefore, established that normal lymphocytes contain at least one, and possibly two, proteins which are indistinguishable from certain of the normal globulins of the blood, and that these proteins are released from lymphocytes to the circulation under circumstances of augmented pituitary-adrenal cortical secretion.³⁴⁻³⁶

Adrenal Cortical Control of the Release of Antibodies From Lymphocytes.—The demonstrated release of globulin from lymphocytes by adrenotrophic and adrenal cortical hormones suggested that these hormones might stimulate an increased production of antibodies in immunized animals. The daily administration of adrenal cortical extract to mice, rats, and rabbits being immunized

with a variety of antigens produced a higher level of antibody in the sera of those animals injected with hormone as compared to the sera of animals receiving antigen alone.^{37, 38}

Because antibodies have been demonstrated in lymphocytes,^{39, 40} augmented dissolution of these cells by adrenal cortical steroids would be expected to increase titer. In hyperimmunized rabbits a single injection of adrenal cortical extract (aqueous or oil), or of adrenotrophic hormone, resulted within six hours in a marked rise in antibodies in the blood.^{37, 38} The maximum effect was observed at nine hours, following which time the titers gradually returned approximately to their previous levels. The data establish that higher titers of antibody appear in the immunized animal at a time after hormone injection when the levels of normal serum globulins are increased in nonimmunized animals. Serum protein alterations are maximum at the time that the greatest amount of lymphocyte dissolution is occurring and when the most striking lymphopenia is present in the blood. Extension of these experiments indicates that the anamnestic response is probably due to the pituitary-adrenal cortical control of the release of antibody from lymphocytes.³⁶ This hypothesis would explain why various nonspecific agents produce an anamnestic response⁴¹ and would correlate this response with the simultaneously occurring lymphopenia.

SIGNIFICANCE OF RESULTS

The acute, absolute lymphopenia observed within a few hours after administration of adrenotrophic hormone is the peripheral manifestation of a sudden release of hormones of the adrenal cortex. This is evidenced by depletion of adrenal cholesterol and sudanophilic material shortly after adrenotrophic hormone injection. In addition, the lymphopenia reflects the marked lymphocyte dissolution occurring concomitantly in lymphoid structures and is, therefore, a result of the failure of delivery of normal numbers of lymphocytes to the circulation. Support for this point of view has been obtained in the experiments of Reinhardt and Li²² who observed a 50 per cent decline in the numbers of lymphocytes in the thoracic duct lymph of the rat within thirty minutes following injection of adrenotrophic hormone. It should be noted that peripheral factors may also be concerned in the removal of lymphocytes, thus contributing to the lymphopenia.⁴²

The lymphopenia and augmented serum globulin levels occur at a time when there is maximum dissolution of lymphocytes in the lymphoid structures (six to nine hours). Following this time, restoration of normal lymphoid structure is evident, lymphocyte dissolution ceases, and blood lymphocytes and serum protein values begin to return to normal. At this time there is also a beginning restoration of the adrenal lipids. Within a relatively few hours, therefore, profound physiologic alterations occur as a consequence of a single stimulation of the adrenal cortex and the effects of adrenal cortical steroids on the structure and function of lymphoid tissue. The rate of these physiologic processes is normally under pituitary-adrenal cortical control. This conclusion is further supported by the fact that in adrenalectomized animals there is a lymphocytosis,^{20, 34} a diminished rate of lymphocyte dissolution,⁴³ and a lower

than normal total serum protein level.^{16, 33} It should be emphasized that the endocrine mechanism is concerned with regulation of the rates of the processes which have been discussed. It is not to be construed, however, that these physiologic processes cease in the absence of the pituitary or the adrenals. In this respect the physiologic reactions influencing lymphoid tissue structure and function resemble other endocrine-controlled phenomena.

Inasmuch as a variety of unrelated stimuli are known to augment pituitary-adrenal cortical secretion, it might be expected that single exposures of an animal to any one of these stimuli would initiate and reproduce the sequence of alterations which have been described previously. Thus, shortly after the initiation of an infection there is adrenal cortical stimulation,^{19, 44-46} an absolute lymphopenia,^{47, 48} lymphocyte dissolution and reticulo-endothelial activation,^{48, 49} and an increase in the serum globulins.⁵⁰⁻⁵⁴ A single injection of a variety of toxic chemical agents, such as, arsenic, benzene, antimony, formaldehyde, colchicine, and foreign proteins, activates the adrenal cortex,^{19, 43} induces a lymphopenia,⁵⁵⁻⁵⁹ lymphocytic degeneration,^{7, 43, 60-63} and augmented serum globulin levels.^{43, 64-66} Anesthetics also produce a portion of this sequence of events.^{67, 68} Radioactive agents, such as, x-rays, radium, and thorium X, are also effective in causing these alterations.^{42, 69-76} Environmental stresses, such as, cold, heat, inanition, trauma, and anoxia, have been shown to reproduce one or more of the series of events under discussion.^{7, 19, 43, 77-84} Finally, physiologic agents normally present in the organism, such as, insulin, epinephrine, histamine, pitressin, and thyroid hormone, may, when administered or when present in excess, augment adrenal cortical activity,^{19, 43} induce a lymphopenia,^{43, 55, 57, 85-87} cause lymphoid tissue dissolution,^{7, 10, 43, 87} and in some instances cause an increase in serum globulins.^{43, 88}

Most of the many kinds of stimuli previously mentioned have been shown to cause adrenal cortical activation, as demonstrated by histologic or chemical study of the adrenal. Moreover, some of these stimuli are without effect on lymphoid tissue in adrenalectomized animals.^{10, 17, 42, 43, 62, 84, 89} The activation of the adrenal cortex is dependent upon the secretion of pituitary adrenotrophic hormone, since certain of these so-called nonspecific stimuli fail to produce any alterations in lymphoid tissue physiology in hypophysectomized animals. It is suggested that a variety of nonspecific influences which have been known for many years to affect lymphoid tissue may be exerting their action through pituitary-adrenal cortical activation.

Many nonspecific stresses may, when applied in large amounts or in great degree, affect lymphoid tissue without hormonal intervention. Thus, it has been shown that high concentrations of benzene will destroy lymphocytes *in vitro*.⁶³ The concentration of benzene required, however, was considerably higher than that which could be obtained in the living organism without producing death. Therefore, the dissolution of lymphocytes following benzene injection could not be accounted for on the basis of a direct action of the chemical on lymphocytes. However, the concentration of benzene which is required to produce lymphocyte dissolution *in vivo* is considerably less than that which will produce similar results *in vitro*. It is recognized that agents less toxic

systemically than benzene may have a direct destructive action on lymphocytes when administered to experimental animals. Agents of this type which have been shown to be effective in causing thymic involution in adrenalectomized animals when given in large, nonphysiologic doses are desoxycorticosterone, testosterone, estrogens, and diethylstilbesterol.^{10, 32, 30} It should be emphasized that most of the data obtained with the use of nonspecific stimuli in relation to lymphoid tissue physiology support the hypothesis that pituitary-adrenal cortical mediation is involved.

A striking example of a stimulus which may exhibit either a direct or an adrenal cortical-mediated effect on lymphoid tissue may be seen from studies with x-rays.^{56, 91} The long-recognized effect of x-rays on lymphoid tissue is, in the case of large doses, a direct action on lymphoid tissue, while in small doses, the lymphocytolytic effect of radiation is dependent on pituitary-adrenal cortical mediation.^{42, 89}

In 1937, Selye⁷ described certain responses, such as, depletion of adrenal cortical lipids, thymic atrophy, gastric hemorrhage, and clouding of the cornea, in experimental animals exposed to a variety of stresses. These reactions were grouped into a syndrome which was termed the "alarm reaction." Selye also noted that repeated exposure to increasing degrees of stress produced an increased degree of resistance against the stress; this phenomenon was called the "adaptation syndrome." The role of the adrenal cortex in the "alarm reaction" was suggested by Selye to be one of protection against histamine which was liberated in augmented amounts during the "alarm reaction." The involution of lymphoid tissue in the stressed animal has now been demonstrated to be due to the augmented secretion of pituitary adrenotrophic hormone.¹⁰ As a result, there occurs an increased release of the steroid hormones of the adrenal cortex, which produce an atrophy of lymphoid tissue.^{11, 15, 18} This atrophy is a consequence of the dissolution of lymphocytes which was described previously.

The extensive literature on the role of lymphoid tissue in resistance led us to suggest³³ that the pituitary-adrenal cortical control of lymphoid tissue structure and function integrated the role of the adrenal cortex and the lymphocyte in resistance. One important manifestation of this relationship is the augmented release of antibody from lymphocytes in circumstances of stress.^{36, 42} The manner in which various factors play a role in resistance and adaptation is not well understood except in the case of the immune globulins.

Although many of the nonspecific stimuli which have been discussed produce an acute lymphopenia, the blood picture may change subsequently to one of lymphocytosis. Acute lymphocyte dissolution and lymphopenia are shortly followed by restoration of normal lymphocyte numbers in lymphoid structures. The duration of the lymphopenia may be dependent upon the degree to which the adrenal steroids are released, the period over which this accelerated release continues, and the rate of operation of processes concerned with the formation of lymphocytes. Various nonspecific stimuli do not affect the pituitary-adrenal cortical mechanism to the same degree, and, therefore, several types of physiologic manifestations of adrenal cortical activation may be seen.¹⁹ In this con-

nection particular attention must be paid to the role of inanition in effecting involution of lymphoid tissue. Calorie restriction is a potent activator of pituitary-adrenal cortical secretion.¹⁹ The effects of inanition on lymphoid tissue have been shown to be mediated primarily by this endocrine mechanism.⁸⁴ In addition, dietary intake will control the supply of materials from which new lymphoid tissue can be formed. It is particularly important to evaluate the inanition factor in nutrition studies designed to elucidate the role of a specific dietary constituent in the growth of lymphoid tissue.

Lymphocyte dissolution may be one of the physiologic stimuli which calls into play factors concerned with the synthesis of lymphocytes. These factors as yet have not been studied adequately. The numbers of circulating lymphocytes in the blood at any time must be a reflection of the balance obtaining among lymphocyte production, lymphocyte dissolution, and peripheral removal of lymphocytes. When the acute effects of the sudden release of adrenal cortical steroids have subsided, the mechanisms concerned with lymphocyte production may manifest themselves to an exaggerated degree. Therefore, the blood picture may alter from lymphopenia to lymphocytosis. The initial lymphopenia produced by most of the nonspecific agents which have been referred to in the previous paragraphs produce lymphocyte dissolution. Therefore, this acute lymphopenia is due to failure of delivery of lymphocytes to the circulation. The subsequent enhanced production of lymphocytes would explain the high level of lymphocytes, following an immediate lymphopenia, which occurs following insulin⁸⁷ or epinephrine injection,⁸⁸ after low doses of x-rays,⁷³ and the lymphocytosis in the recovery phase of acute infectious diseases.^{92, 93} Blood lymphocyte pictures in disease may be better understood when interpreted in the light of the demonstrated function of lymphoid tissue and its peripheral manifestation, the numbers of circulating lymphocytes.

Many of the same stimuli which have been previously cited as augmentors of pituitary-adrenal cortical secretion, of lymphoid tissue dissolution, of the degree of lymphopenia, and of serum protein levels are also known to increase antibody titers in immunized animals.^{1, 41} This enhancement of titer by non-specific stimuli is known as the anamnestic reaction. These relationships suggested that the anamnestic response was dependent upon the ability of these agents to increase adrenal cortical hormone secretion. Data obtained^{36, 42, 89} establish clearly that an enhancement of antibody titer occurred when adrenal cortical preparations were administered to previously immunized animals having no circulating antibody. Adrenotrophic hormone was highly active in the normal but not in the adrenalectomized animal. Certain toxic agents, potassium arsenite, benzene, and low doses of x-rays produced the anamnestic reaction in normal animals. These agents were without effect in the absence of the adrenals. All of the adrenalectomized animals had demonstrable antibodies in extracts of lymphocytes from their lymphoid tissue. The pituitary-adrenal cortical mechanism is essential for the release of antibodies from lymphocytes except under those conditions in which there is a direct effect of the toxic agent on lymphocytes, such as high dose of x-rays in adrenalectomized animals.^{42, 89}

The role of the adrenal cortex in controlling the rate of release of lymphocyte constituents correlates the functions of the adrenal and of the lymphocyte in resistance. The participation of the adrenal cortex is dependent upon its stimulation by pituitary adrenotropic hormone.

CONCLUDING REMARKS

In the opening statements of this presentation, attention was called to the paucity of knowledge concerning the fate and function of the lymphocyte and the physiologic control of lymphoid tissue. One of the fates of the lymphocyte elements is a dissolution of many of these cells in the lymphoid structures. This dissolution often results in the disintegration and removal of the structural material of these cells. Some lymphocytes may shed portions of their cytoplasm into the surrounding lymph without death of the residual nuclei; under these circumstances, regeneration of normal amounts of cytoplasm may follow. The cytoplasm yielded to the lymph by the lymphocyte contains gamma globulin and, in the immunized animal, antibody. Gamma globulin is found within lymphoid structures, is present in lymphocytes, and its rate of release from these cells is under control of pituitary-adrenal cortical secretion. As a consequence of this hormonal control of the rate of lymphocyte dissolution, the numbers of lymphocytes in the blood and in lymphoid tissues is influenced by the degree of adrenal cortical activity.

PURPURA FOLLOWING ESTROGEN THERAPY, WITH PARTICULAR
REFERENCE TO HYPERSENSITIVITY TO (DIETHYL)
STILBESTROL AND WITH A NOTE ON THE
POSSIBLE RELATIONSHIP OF PURPURA
TO ENDOGENOUS ESTROGENS

C. J. WATSON, A. L. SCHULTZ, AND H. M. WIKOFF
MINNEAPOLIS, MINN.

THE literature indicates that the administration of estrogenic substances, and particularly stilbestrol, while at times productive of nausea and vomiting, does not cause serious toxicity in human beings. Thus, Shorr and co-workers,¹ Davis,² Davis and Boynton,³ and MacBryde and associates⁴ made careful observations of the blood in large series of women receiving 1 to 5 mg. of stilbestrol daily over long periods of time; they failed to find any significant changes in the blood or any evidence of a hemorrhagic tendency. The study of Karnaky⁵ seems even more convincing in this respect. He gave remarkably large doses of stilbestrol to 136 women and eighty-six children. The adults received as much as 500 mg. at a single dose, 250 mg. once or twice weekly, or 100 mg. daily. The majority of the children were given 1 to 5 mg. daily; eight, however, received 10 to 25 mg. per day or every other day for periods of one to eight months. Karnaky relied on the sedimentation rate and complete blood counts to detect toxic effects. None were observed, and he therefore concluded that stilbestrol is entirely safe. Nevertheless, certain cases have been reported in the literature which indicate that occasional individuals may exhibit an idiosyncrasy or sensitivity to stilbestrol or other estrogenic substances, with resultant injury of the liver or bone marrow. Loftis⁶ reported the case of a 44-year-old white woman who developed purpura over the lower extremities and bleeding from the gums while receiving weekly injections of an estrogen. The purpura disappeared within three weeks after the drug was stopped. Repeated trials with varying dosages always caused recurrence of purpura. Laboratory studies, including platelet counts, revealed nothing abnormal. A bone marrow examination was not reported. Chevalier and Umdenstock⁷ observed a case of fatal myelophthisis following injections of large amounts of estradiol benzoate. This patient had received estradiol repeatedly over a period of ten years because of recurrent pruritus vulvae. The last course consisted of twenty injections of 10 mg. each in a two-week period. Shortly thereafter, the patient developed a profound anemia, leucopenia of 800 cells per cubic millimeter with 30 per cent neutrophils, and an outspoken purpura with 56,000 platelets per cubic millimeter. Herbst⁸ observed purpura in two men receiving estradiol propionate for cancer of the prostate. There was no reduction of platelets in either case, and it was stated that the purpura was controlled by administration of calcium gluconate.

From the Department of Medicine, University of Minnesota Hospital.

Instances of probable hepatotoxic effect of stilbestrol in human beings have been reported by Elias and Schwimmer⁹ and Seligman.¹⁰ The former case is of special interest in that the authors were able to demonstrate a distinct allergy to stilbestrol in their patient. They believed that the hepatocellular impairment was allergic in character. Jaundice was of relatively short duration and recovery was apparently complete.

A considerable literature has accumulated with respect to the effect of stilbestrol and other estrogens on the blood and blood-forming organs and the liver, in animal experiments. It is evident from these studies that there is a distinct difference in the sensitivity of different species. Arnold¹¹ showed that daily intramuscular injections of 4 to 10 mg. of stilbestrol in dogs commonly produced severe aplastic anemia and thrombocytopenic purpura. Tyslowitz and Dingemans¹² found that dogs tolerated 1 mg. of estradiol or stilbestrol daily during a period of nine months without exhibiting any significant changes in the blood, but if given 5 mg. of either estrogen daily, a prompt fall in all blood elements occurred within one to three weeks after the injections were begun. The erythrocyte count and hemoglobin fell rapidly before any evidence of hemorrhage was noted. The platelets then dropped to very low levels and severe purpura occurred. The leucocytes showed an initial rise followed by a marked decrease in the number of granulocytes. Bone marrow studies in these dogs revealed a marked hyperplasia involving all of the cellular elements. These investigators¹² concluded that the estrogen caused a primary injury to the bone marrow followed by changes in the peripheral blood. Their results were confirmed by MacBryde and co-workers⁴ and Crafts.¹³ Castrodale and associates¹⁴ compared the effect of stilbestrol and estradiol in dogs, using both parenteral and oral routes of administration, and found that thrombocytopenia and hemorrhage occurred sooner and that the survival time was shorter in those animals receiving estradiol. The onset of the blood changes and of purpura was delayed in the animals receiving the estrogen orally, but the severity was just as great after their appearance. They also noted that the bone marrow initially showed an increase of the myeloid elements with decreased areas of erythropoiesis, followed by a generalized hypoplasia. The megakaryocytes were markedly decreased early in the course of the experiment. The effect of stilbestrol in rats is evidently much less marked. A mild decrease in platelets early in the course of experiments in which large amounts of stilbestrol were injected was observed by von Haam and co-workers,¹⁵ but there was no purpura nor any significant change in the leucocytes. The rat bone marrows, however, were markedly hyperplastic. Page and associates¹⁶ implanted pellets of stilbestrol subcutaneously in rats and failed to notice any subsequent changes in the blood or bone marrow. Jacobson¹⁷ injected relatively large doses of estradiol in white mice and found a moderate decrease in hemoglobin and red blood cells in the peripheral blood. He noted that the bone marrow of the mice showed a marked replacement of the marrow spaces by endosteal new bone formation, the remaining areas of active marrow being hyperplastic. Crafts¹³ and Tyslowitz and Hartman¹⁸ were unable to produce any significant changes in the

blood or bone marrow of Rhesus monkeys, in spite of the administration of large amounts of estradiol or stilbestrol.

The effects of estrogens on the liver in animals has not been as extensively studied. Castrodale and associates¹⁴ noted fatty metamorphosis and focal necrosis in the livers of many of their series of dogs receiving relatively large amounts of stilbestrol or estradiol, either orally or parenterally. Roberts and co-workers¹⁹ later reported that large doses of estrone or estradiol benzoate produced changes in the liver, bone marrow, and peripheral blood of dogs, which were indistinguishable from those produced by stilbestrol. Hepatic changes consisted of fatty metamorphosis and hydropic degeneration.

It should be emphasized that in all of the experimental work which has been mentioned, the amounts of estrogenic substance necessary to produce evidence of injury were greatly in excess of the therapeutic dose in human beings. The purpose of the present report is to describe five cases in which purpura was first noted following estrogenic therapy. Four of these were in women, one was in a man. The latter individual also exhibited marked evidence of hepatic functional impairment.

CASE REPORTS

CASE 1.*—E. S., a 55-year-old housewife, was first admitted to the University Hospital in March, 1943, because of weakness, menorrhagia, and purpura.

The patient had noted the onset of the menopause in the fall of 1936; it was characterized by hot flashes, increasing nervousness, weakness, and cessation of menses. In 1937 she consulted a local physician who gave her several intramuscular injections of amniotin in oil. She had little improvement of the symptoms and in June, 1939, consulted another physician. At this time intensive estrogen therapy was begun, and from June, 1939, until March, 1943, she received many intramuscular injections of estrone and estradiol. It has not been possible to determine the exact amount. In September, 1941, in addition, oral stilbestrol therapy was commenced. The patient received from 1 to 1.5 mg. of stilbestrol daily until March, 1943. In June, 1942, the patient was seen by the physician because of an episode of uterine bleeding which lasted three days. At this time she also complained of bruising very easily. The hemoglobin was found to be 80 per cent; the red blood cells were 4,000,000 per cubic millimeter; the leucocytes, 2,400 per cubic millimeter; and the platelets, 15,000 per cubic millimeter. Bleeding time by the Duke method was 15 minutes. The patient was treated with several blood transfusions, vitamin K, liver extract, and peetin, but moderate uterine bleeding lasted three to four days and recurred regularly each month. She continued to bruise easily on slight trauma.

In December, 1942, the patient first noticed petechiae over the legs, forearms, and chest. In February, 1943, there was a profuse uterine hemorrhage, and she was admitted to a private hospital. The examination of the blood at this time showed the hemoglobin to be 60 per cent; the red blood cells were 3,000,000 per cubic millimeter; the leucocytes, 2,900 per cubic millimeter; and the platelets, 8,700 per cubic millimeter. During this period of hospitalization the patient was given several blood transfusions and five deep x-ray treatments to the ovaries. She was discharged after nine hospital days. Uterine bleeding stopped on March 15, 1943, after four weeks of continuous rather severe hemorrhage, but the purpura persisted, and on March 25, 1943, she was admitted to the University of Minnesota Hospital. It should be noted that the patient had continued to take stilbestrol up to this time.

The past history revealed nothing of significance. The catamenia had been entirely normal prior to the menopause, and there was no previous indication of a hemorrhagic tendency.

*This case was studied through the courtesy of Dr. H. W. Quist, Minneapolis, Minn.

Physical examination revealed numerous petechiae over the body and several large ecchymoses over the patient's legs, chest, and forearms. The spleen was barely palpable on deep inspiration. There were no other findings of significance.

The hemoglobin was 10.8 grams per 100 c.c.; the leucocytes were 2,000 per cubic millimeter; the reticulocytes, 1.5 per cent; and the platelets, 160,000 per cubic millimeter. The bleeding time by the Duke method was 42 minutes; the prothrombin time was normal. The cephalin-cholesterol flocculation test was 3 plus at 24 hours. A sternal bone marrow puncture revealed generalized hypoplasia of all the cellular elements of the bone marrow. Megakaryocytes were very scarce and showed degenerative changes.

All estrogenic therapy was stopped. The patient was given several blood transfusions, and was discharged in relatively good condition. It is noteworthy that she was complaining rather severely of hot flashes and that she wished very much to take additional stilbestrol for relief. She was advised strongly not to do this.

The purpura gradually disappeared, and the patient was relatively free of hemorrhages so far as can be determined from April, 1943, until July, 1944, when petechiae and ecchymoses again appeared over the legs, arms, and chest. It may be noted, however, that the platelets were repeatedly found to be reduced during this interval: 2,200 on April 16, 1943; 38,000 on Aug. 24, 1943; 6,400 on Oct. 18, 1943; and 148,000 on Feb. 10, 1944. The uterine bleeding did not recur. In September, 1944, she was given twelve roentgen treatments of ten minutes each to the ovaries, a total of 3,474 r.; the purpura persisted, however, and the patient was readmitted to the University Hospital in December, 1944. Physical examination at this time was essentially negative except for marked purpura over the legs, forearms, and chest. The hemoglobin was 11.5 grams; the leucocytes were 2,050 per cubic millimeter with 62 per cent neutrophils. The platelets were 62,000 per cubic millimeter. The prothrombin time was again normal and cephalin-cholesterol flocculation test at this time was negative. The bleeding time was markedly increased. Several sternal bone marrow punctures were attempted, but no marrow could be aspirated. After four days in the hospital, the patient was discharged and has been followed in the Out-patient Clinic until the present time. She has persisted in having purpura of moderate degree, and the platelets have varied on a number of occasions between 30,000 and 120,000 per cubic millimeter. The leucocytes have varied between 1,800 and 3,100 with 50 to 65 per cent neutrophils. The hemoglobin ranges between 10.5 and 12.5 grams per 100 c.c., and the red blood cells range between 3.8 and 4.5 million per cubic millimeter. Trial of various substances has been made, including refined liver extracts by intramuscular injection, whole desiccated liver by mouth, and folic acid by injection in amounts ranging up to 50 mg. per day. None of these has had any demonstrable effect.

This patient, then, has a chronic thrombocytopenia purpura and leucopenia, which is remarkably stable at a level permitting a reasonable degree of activity but which, nevertheless, interferes with her life to a considerable extent and threatens at any time to become more severe.

CASE 2.—Y. T., a 53-year-old housewife, was admitted to the University Hospital in December, 1944, because of purpura over the arms, legs, and chest.

The patient had the onset of the menopause in January, 1942, when the menses became irregular and profuse and she began to have increased nervousness, weakness, and hot flashes. In May, 1942, she had an episode of severe menorrhagia. Hysterectomy and bilateral salpingo-oophorectomy were performed at a private hospital, and at this time, May, 1942, oral stilbestrol therapy of one tablet daily was begun and continued until November, 1944. In November, after two and one-half years of continuous stilbestrol therapy, the patient first noticed petechiae and ecchymoses over the arms, legs, and chest. These persisted and she entered the University of Minnesota Hospital on Dec. 13, 1944. The past history revealed nothing of significance other than a mild arthritis of the cervical spine for which intravenous injections of streptococcus vaccine were given during October and November, 1944. This will be considered again in the following.

The physical examination revealed nothing of significance other than many petechiae and several ecchymoses over the legs, arms, and chest.

The hemoglobin was 10.3 grams; the red blood cells were 4,000,000 per cubic millimeter; the leucocytes, 5,250 with 57 per cent neutrophils; and the platelets, 70,000 per cubic millimeter. The cuff test was negative. The bleeding time by the Duke method was 16 minutes. A platelet count performed one week later was 90,000 per cubic millimeter. Stilbestrol therapy was stopped when the patient entered the hospital. The purpura rapidly improved, and after three days she was discharged to the Outpatient Clinic where she has been followed to the present time. Within two weeks from the time of discharge the petechiae had entirely disappeared. On Dec. 26, 1944, the platelet count was 180,000 per cubic millimeter; on Jan. 2, 1945, 210,000; and on March 14, 1945, 180,000. The sternal bone marrow obtained during the hospital admission revealed a marked hyperplasia involving chiefly the granulocytes. The megakaryocytes were also increased in number. The brom-sulfalein test (5 mg. per kilo at 45 minutes) was negative but the cephalin-cholesterol flocculation test was 3 plus in 48 hours. The urine urobilinogen was normal.

There was no recurrence of purpura until March 1, 1947. Shortly before this, the patient had taken benzestrol¹⁰ because of persistent hot flashes. The onset of purpura was noted three days after the benzestrol was started. The drug was discontinued at once and after four days the purpura began to disappear. By March 25, it was no longer evident. On March 11 when it was still widespread, the platelets numbered 165,000 per cubic millimeter and the cuff test was strongly positive.

Streptococcus vaccine therapy was resumed in 1945 and has been continued irregularly until the present time. There has been no evidence of any recurrence of the purpura except on the one occasion following benzestrol. Thus, it appears improbable that the vaccine had any relation to the thrombocytopenia.

CASE 3.*—S. G., a 23-year-old housewife, had been well except for irregularity of the menstrual periods. The interval had always been greater than thirty days, and since her marriage in 1943, the periods were even more irregular, there having been not more than eight or ten periods in the two years. On Feb. 15, 1945, because of not having had a period since October, 1944, the patient consulted a physician who gave her $\frac{1}{2}$ c.c. benzestrol.¹⁰ This dose was repeated on Feb. 21 and 22 and on March 6. On April 4, she was given 2.5 mg. of dimenformin benzoate, and on April 5, 12.5 mg. of trigestin. One week later menstruation commenced and lasted for five days. Two days after termination of the period a "rash broke out all over her body." She noticed that it was worse on the legs and hands but that it was present everywhere to at least a slight degree. She also noted a few bruises on various parts of the body.

The past history did not reveal anything of significance. The family history was of interest in that a sister died at the age of 23 of leucemia. The patient has two brothers and one sister living and well. Her parents are also well.

She has had occasional headaches, for which she takes a tablet composed of acetophenetidine, aspirin, and caffeine. She has taken one of these about every two weeks since October, 1944.

The physical examination revealed nothing other than a diffuse purpura. Multiple petechiae were present with increasing frequency toward the distal portions of the extremities, most marked on the lower legs and ankles. However, there were a few on the face, chest, abdomen, arms, hands, and thighs. The liver and spleen were not palpable.

The hemoglobin was 13.7 grams; the red cells were 4,150,000; the leucocytes, 7,200 per cubic millimeter with 61 per cent neutrophils; the platelets, 12,100; the bleeding time by the Duke method 24 minutes. A repeat platelet count was 20,000; the prothrombin was 100 per cent of normal. On April 25, there was no evidence of further spread of the purpura, but the platelets were only 11,000. On June 6, the platelet count was 13,200, the bleeding time 23 minutes. The bone marrow obtained by sternal puncture was said to reveal nothing abnormal. On July 27, 1945, the platelet count was 33,000, and on August 9, 40,000. At this time the purpura had almost entirely disappeared. On November 13, a few new petechiae

*This case is reported through the courtesy of Dr. J. Garrott Allen of the Department of Surgery and the Metallurgical Laboratory, University of Chicago.

were observed. The irregular menstruation with long intervals between the periods has continued. The platelet count on Nov. 13, 1945, was 12,000. On Jan. 2, 1946, the patient was seen because of recurrence of petechiae in moderate number, especially on the legs. The patient was last observed on Feb. 16, 1946. At this time the hemoglobin was 10.9 grams; the red blood cells were 3,880,000; the leucocytes, 5,700 with 62 per cent neutrophils; the platelets, 15,500. Only a few petechiae were noted.

CASE 4.*—M. C. was a 79-year-old retired businessman. In 1939, at the time of transurethral resection, it was found that the patient had a carcinoma of the prostate. Stilbestrol was commenced on July 3, 1942, 0.5 mg. daily. From Nov. 17, 1943, until shortly before admission to the hospital, he took, somewhat intermittently, 3 mg. daily. The breasts had become distinctly enlarged. From time to time during this period the patient had received small amounts of sulfadiazine because of a urinary tract infection. He had not, however, received any sulfadiazine for three months prior to death and for one month prior to the first appearance of purpura. Ecchymoses first became evident on the extremities and neck about Feb. 25, 1946. Because of increasing purpura with some very large ecchymoses, particularly over the abdomen, the patient was admitted to the hospital on March 10, 1946. The hemorrhages were in the form of large ecchymoses and even considerable extravasations of blood under the skin. One massive extravasation was noted over the lower abdomen extending down into the pubic area and including the scrotum, also down onto the thighs. There were numerous ecchymoses elsewhere but small petechiae were very rare. There was no jaundice at the time of admission. The liver and spleen were not palpable, and there was no lymphadenopathy. There were no evidences of metastases to the bones. (X-rays of spine and pelvis were negative.) The platelet count was 40,000 on the day following admission. On the next day it was found to be 70,000. The prothrombin time was 17 per cent of normal. The serum albumin was 2.6 grams per cent; the serum globulin, 2.3. The cephalin-cholesterol flocculation test was 3 plus in 24 hours. The urine urobilinogen was 42 mg. in 24 hours (normally not above 3.5 mg.). The later course in the hospital was characterized by retinal hemorrhages, hemoptysis, and gastrointestinal bleeding, in addition to further bleeding into the skin. Coincident with transfusions and vitamin K, the prothrombin time came up to 80 per cent of normal, following which there was a temporary cessation of hemorrhages. Later, however, in spite of continued vitamin K administration, the prothrombin time dropped to 30 per cent and the generalized hemorrhagic tendency recurred. During the last six weeks in the hospital, the platelet count gradually rose to 150,000, but the bleeding persisted. An additional feature of interest that was not explained was a marked hypocalcemia with tetany. The serum calcium was 6.8, and on frequent occasions there was manifest tetany requiring injection of calcium. Death was believed to be due to anemia and exhaustion. Slight jaundice was observed in the last ten days of life. There was no evidence of steatorrhea.

Necropsy in this case revealed very little. The prostate was small and rather soft but exhibited definite adenocarcinoma microscopically. The liver was described as being "granular and firm," but not enlarged. Microscopically the sections of the liver revealed nothing other than mild passive congestion. The bone marrow was not examined.

CASE 5.†—H. G. was a 45-year-old housewife. Menstruation first became irregular in February, 1942. There was no period in May, 1942, and again from July to October, although during this interval one brief period of rather profuse bleeding for two hours occurred. In January, 1943, the patient was overemotional, had swelling of the hands, tingling of the skin, chills, sweats, and hot flashes. She was given 0.5 mg. of stilbestrol daily for one week, together with nembutal, $\frac{1}{2}$ grain three times daily. She was seen two weeks later, at which time the nervousness and exhaustion, and also the hot flashes and sweats, were considerably improved. Stilbestrol in an amount of 0.5 mg. daily was continued for one week. From this time on the stilbestrol was given intermittently in the same dose for

*This case was seen in consultation with Dr. D. P. Head to whom the authors acknowledge their gratitude for permission to report the findings which are given.

†This case was studied through the courtesy of Dr. Henry L. Ulrich, Minneapolis, Minn.

a period of four months. In August, 1944, when the patient was next seen, perspiration was marked and there were frequent dizzy spells, particularly on waking up in the morning. Stilbestrol was resumed in a dose of 0.2 mg. daily. She was not seen again until March, 1945. The same dose, namely, 0.2 mg., was prescribed again. The patient was also given calcium lactate, 5 grains three times a day, and $\frac{1}{2}$ grain of nembutal three times daily. She was next seen in June, 1945, and stilbestrol was given again, 0.2 mg. daily. In August she was given 2,000 units of estrone hypodermically. This dose was repeated in November, 1945, the stilbestrol being taken intermittently in the interval. Bleeding was first noted in June, 1946. This was from the gums and uterus. From this time on there has been recurrent uterine bleeding, also intermittent hemorrhage from the gums and nose, and purpura of the skin. Numerous petechiae and ecchymoses have been noted on a number of occasions.

The physical examination revealed nothing of significance in other respects. The spleen and liver were not palpable and there was no lymphadenopathy.

Blood examination on June 6, 1946, revealed the following: Hemoglobin 80 per cent, red blood cells 4,430,000, leucocytes, 3,700, 49 per cent neutrophils, 36 per cent lymphocytes, 11 per cent monocytes, 3 per cent eosinophiles, and 1 per cent basophiles. On Sept. 24, 1946, the hemoglobin was 14.5 grams; the platelet count, 121,000 per cubic millimeter; the bleeding time, 5 minutes, 2 seconds (Duke method); the cuff test, markedly positive, 45 petechiae in a circle 1 inch in diameter on the forearm; the prothrombin time by the Quick method, 12.7 seconds (control, 12.4). Since this initial study, frequent platelet counts, bleeding times, and cuff tests have been carried out with essentially the same findings, regardless of the degree of purpura exhibited by the patient at the particular time. So far as is known she has not received any estrogen therapy since June, 1946. The purpura has not been alarming up to the present time, and the patient has been able to continue her activities on a limited scale.

STUDIES OF SKIN SENSITIVITY TO ESTROGENIC SUBSTANCES

Three of the previously described patients (Cases 1, 2, and 5) were available for skin tests to determine possible sensitivity to estrone and stilbestrol. Twenty-five individuals, either normal or suffering from various diseases, served as controls. Sixteen of these were tested for sensitivity to estrone, the remainder to stilbestrol. In each instance the test consisted of injecting intradermally 0.1 c.c. of a 0.2 per cent suspension in physiological saline. The same amount of the vehicle alone was injected in the opposite arm as a control. Observations of reactions were made at 30 minutes, 1 and 4 hours, and 24 hours, as noted in the following. The results of the tests are given in Table I. It is seen that Cases 1 and 2 exhibited distinct skin sensitivity to stilbestrol, while Cases 2 and 5 were sensitive to estrone. In none of these three cases was there any sensitivity to the vehicle. The reactions in each instance were of erythematous type, only slightly raised and without definite whealing. Their appearance suggested the presence of an active capillary or arteriolar hyperemia without transudation. Two of the control cases exhibited sensitivity to the estrone solution and one of these was positive to the solution of stilbestrol, but both showed equally positive reactions to the vehicle, so they cannot be classified as positive to the estrogens. Thus, it is evident that the only positive reactors among the twenty-eight individuals were the three with purpura, Cases 1, 2, and 5 of the present series. So far as could be determined from the records of the control individuals none had at any time received estrogen therapy.

Prausnitz-Küstner passive transfer was attempted in Cases 2 and 5 with estrone and in Cases 1 and 2 with stilbestrol, but this was uniformly negative.

TABLE I. SKIN SENSITIVITY TO STILBESTROL AND ESTRONE

CASES IN PRESENT SERIES			CONTROL TEST (0.1 G.O. NORMAL SALINE)				ESTRONS			STILBESTROL

Thus, it is questionable whether the skin reactions which were noted were due to circulating antibody. Precipitin tests were not carried out due to the insolubility of stilbestrol and estrone in water. The nature of these skin reactions is not understood but it seems likely that their significance is fundamentally related to the clinical manifestations in these cases, especially in view of the relatively large number of negative controls. The possibility of a specific tissue sensitivity is considered.

DISCUSSION

While the cases described in the foregoing cannot be accepted as proving a causal relationship between stilbestrol or other estrogenic substances and purpura, they do, nevertheless, suggest that such a relationship may at times exist, and they point to the need of greater conservatism in the administration of these substances. They also indicate the desirability of frequent observations with respect to the possible appearance of a hemorrhagic tendency in patients receiving continued estrogenic therapy. It is believed justified, in view of the present results of the skin sensitivity studies, to skin test patients in advance of the prescribing of estrogenic substances. In this connection, however, we recognize that the sensitivity shown by the present cases may have been acquired rather than inherent. In any event the appearance of signs of bone marrow or capillary injury, or of hepatic functional impairment, would appear to warrant discontinuance of estrogen therapy and the application of skin tests to determine possible sensitivity to estrogenic substances. It is clear that a relationship in these cases would have to be regarded as an idiosyncrasy or hypersensitivity, possibly analogous to the occasional case of neutropenia or agranulocytosis which follows amidopyrine, or the thrombocytopenic purpura at times seen following sedormid therapy, and concerning which a number of papers have appeared in the literature. Evidence as to the usually innocuous character of stilbestrol was cited at the outset. The onset of purpura following the exhibition of stilbestrol and its disappearance and reappearance after discontinuance and readministration, as in Case 2 of the present series and in the case reported by Loftis,⁶ lend further support to the belief in a causal relationship. The regular production of thrombocytopenic purpura in dogs with amounts of stilbestrol larger than those commonly used in human therapy is quite compatible with the concept that the occasional cases of purpura noted in human beings after stilbestrol therapy represent idiosyncrasies or hypersensitivity to the drug. The possibility cannot be excluded that the purpura in Case 3 was related to the occasional ingestion of acetophenetidin.

It is also of interest that a number of papers have called attention to the association of purpura with menstruation.^{21-24, 26, 28-30} In these studies it was at times noted that the platelet counts were normal between the periods, only to decline at the beginning of each menstruation and with the onset of purpura. With the cessation of menstruation, the platelet counts returned to normal and the purpura disappeared. Nagy²² reported two cases of thrombocytopenic purpura in which irradiation of the ovaries was followed by an increase of platelets with disappearance of purpura and menorrhagia. For these instances,

Nagy suggested the term "purpura dysovarica." As a matter of fact, it was chiefly because of Nagy's report that radiation was given to the ovaries in Case 1 of the present series. No apparent benefit was noted, but it is quite likely that the bone marrow injury in this instance was exogenous while it would appear to have been endogenous in Nagy's cases. In this connection, attention may be called to a case reported by Leschke and Wittkower.²⁴ A 23-year-old woman had had severe menorrhagia since onset of the menses at the age of 11. When the patient reached the age of 22, the platelets were found to be 3700 per cubic millimeter. The surgeon removed the uterus and a cystic right ovary. This was followed by prompt cessation of the hemorrhagic tendency, and for two years there was no difficulty, after which time, however, the purpura recurred.

The relative frequency of thrombocytopenic purpura in women after puberty has been stressed repeatedly.^{26, 28} Purpura is relatively common during pregnancy and has often constituted a severe complication. A number of the cases collected from the literature by Rushmore²⁷ exhibited purpura only during pregnancy, and some of them had a recurrence of purpura in subsequent pregnancies. On the other hand, Evans and Perry²⁵ observed a case in which a thrombocytopenic purpura disappeared entirely during pregnancy, only to reappear after delivery.

There is disagreement as to the platelet counts of normal women during their menstrual cycles, Genell³¹ and Pohle³² having reported a noticeable decrease in the platelet count at the beginning of each period and Damashek³³ having found just the opposite. David³³ emphasized the occurrence of hemorrhages and of positive Rumpel-Leede (capillary fragility) tests during menstruation. This question obviously deserves further study.

The possibility of sensitivity to endogenous estrogen, as suggested by the foregoing, is supported in some measure by the fact that two of the cases in the present series exhibited skin sensitivity to estrone, a natural estrogenic substance. One might assume that in certain individuals, a tissue, perhaps a capillary sensitivity, if not inherent, becomes established as time goes on. Evidence is lacking as to the nature of this sensitivity and the manner in which it might operate to produce purpura. The concept of sensitivity to endogenous estrogen has been elaborated by Zondek^{34, 35} under the general appellation of "endocrine allergy." Zondek has demonstrated skin sensitivity to natural estrogens in a variety of pathologic states and has shown that desensitization is frequently beneficial.

The possibility of hepatotoxic effect of stilbestrol is suggested both by the animal experiments and the human cases previously mentioned.^{9, 10} In Case 2 of the present group the cephalin-cholesterol flocculation test was positive in association with the thrombocytopenic purpura and negative after discontinuance of stilbestrol and disappearance of the purpura. The possibility exists, however, that there was a mild liver injury secondary to the purpura and unrelated to the stilbestrol. Case 4 of the present series was of particular interest because of the association of a severe hemorrhagic state with thrombocytopenia and hypoprothrombinemia, together with other evidence of liver

functional impairment following long continued use of stilbestrol for carcinoma of the prostate. The autopsy findings in this case did not indicate that the hemorrhagic state was related either to the carcinoma or to any demonstrable liver disease of ordinary type.

SUMMARY AND CONCLUSIONS

1. Five cases are reported in which purpura followed the administration of stilbestrol or other estrogenic substances. Four of these were in women being treated for menopausal symptoms or amenorrhea; one was in an elderly man with carcinoma of the prostate, without evidence of metastases.

2. In four of these cases the estrogen therapy, mainly stilbestrol, had been given for long periods, ranging from two and one-half to seven years. In one of these four, however, there were long intervals during a total of three years, in which none was given. In the fifth case estrogens were given parenterally, intermittently over a two-month period.

3. The purpose of reporting these five cases is simply to call attention to the possibility of a causal relationship between stilbestrol and other estrogens and purpura. Evidence of hypersensitivity to stilbestrol or estrone or both, was manifested in each of the three cases available for skin testing, although absent in twenty-five control individuals. Circulating antibody could not be demonstrated by passive transfer. Nevertheless, the possibility must be considered that hypersensitivity to exogenous or endogenous estrogens may at times constitute the major factor in the production of purpura.

4. The literature relating to estrogenic substances is discussed from the following standpoints: (a) The reported cases of supposed toxic effect in human beings, in which abnormalities related to the liver or blood were noted; (b) the experimental production of purpura and hepatic injury in animals by means of their administration; and (c) the question of effect of endogenous estrogen in the production of purpura.

ESSENTIAL THROMBOCYTOPENIC PURPURA

AUTOPSY FINDINGS IN THIRTY-SIX CASES

AMBROSE J. HERTZOG, PH.D., M.D.

MINNEAPOLIS, MINN.

THE files of the pathology department of the University of Minnesota contain the records of over 51,000 autopsies. Most of the patients with purpura listed are secondary types following such diseases as leukemia, meningococcic sepsis, bacterial endocarditis, scarlet fever, measles. Some of them are examples of drug idiosyncrasies. After eliminating these cases, there remained thirty-six that belonged to the essential or idiopathic group. Wiseman, Doan, and Wilson¹ and Wintrobe² have given rigid criteria for the definition of essential thrombocytopenic purpura from the clinical and anatomical viewpoint.

The average age of these thirty-six patients was 30.5 years. Women predominated, twenty-four to twelve men. This confirms the findings in the literature that essential thrombocytopenic purpura is primarily a disease of young people and that the women show a marked preponderance. It is possible that the physiologic decrease in the number of platelets during menstruation may be a predisposing factor for the development of the signs of purpura in women when associated with other causative factors that decrease the platelet level. Hormones may be another factor. The average platelet count in these cases was 55,000 per cubic millimeter. The bleeding times varied from ten minutes to four hours, the coagulation time from three to eight minutes.

The gross findings at autopsy, apart from the hemorrhages that have resulted in the death of the patient, are meager. The body may have the anemic appearance that follows profuse or prolonged hemorrhage. The degree of anemia may be very severe. The hemorrhages may be so widespread that it is difficult to consider any part of the body as the principal site of the bleeding. There were twelve such cases in the total number of thirty-six. In twelve of these death was due to intracranial hemorrhages. Unconsciousness and death may occur within a short time after the onset of acute purpura. Most of the hemorrhages were located beneath the dura mater and were diffusely scattered over the surfaces of the brain. At times it was difficult to decide whether the hemorrhage was extrinsic or intrinsic to the arachnoid membrane. The fact that some of the hemorrhages had the appearance of a subdural hematoma with a tendency towards organization of the clot to the inner surface of the dura would tend to show that most of the hemorrhages are subdural rather than subarachnoid in origin. Occasionally intracerebral hemorrhages may occur with or without an associated subdural hemorrhage. The intracerebral and intracerebellar hemorrhage may vary from petechiae to massive hemorrhages. Once the diagnosis of essential thrombocytopenic purpura is established the

From the Department of Pathology of the University of Minnesota Medical School and the Minneapolis General Hospital.

risk of death from fatal hemorrhage is probably higher than the operative mortality of a splenectomy in the hands of capable surgeons.

In two cases bleeding from the gastrointestinal tract predominated. The hemorrhages varied from massive ecchymosis to petechiae involving the mucosa, walls, and serosa of the stomach, intestine, and colon. In one case the principal bleeding was from the urinary tract. The bleeding was largely from the mucosa of the renal pelvis and bladder. Large perirenal hematomas were not uncommon in other cases. Nine patients continued to suffer from widespread hemorrhages following splenectomies. In one patient, who died after a splenectomy, an accessory spleen that weighed 12 grams³ was found at autopsy.

The earlier investigators centered their interest largely upon the spleen. The normal adult spleen weighs approximately 150 grams. The average weight of twenty spleens in patients over 20 years of age in this series was 232 grams. The smallest weighed 103 grams and the largest 365 grams. It is seen that the spleen is only slightly enlarged and is not palpable. Pemberton⁴ in a series of fifty-seven splenectomies for thrombocytopenic purpura found the average weight of the spleen to be 201.25 grams. However, he included in this series a spleen which weighed 700 grams in a 10-year-old child.

The histologic findings in the spleen are negligible. The majority of spleens had a fairly normal histologic structure. The Malpighian corpuseles are prominent as observed commonly in young people. The sinuses of the pulp are frequently filled and distended with small groups of red blood cells. Small collections of neutrophils are fairly common. However, this is not sufficient to speak of a true splenitis. Slight fibrosis of the pulp was observed in one case. Nickerson and Sunderland⁵ in five patients with essential thrombocytopenic purpura attached importance to the finding of megakaryocytes in the sinuses of the pulp. Megakaryocytes are occasionally seen in the sinuses of the pulp. The bone marrow in these patients usually contained large numbers of similar cells. Younger forms of megakaryocytes are difficult to distinguish from large reticulum cells of the splenic sinuses in the usual hematoxylin and eosin preparations. The lack of other signs of myeloid metaplasia in the spleen would indicate that these megakaryocytes are embolic from the bone marrow. Kaznelson⁶ reported finding phagocytosis of the platelets by the reticulo-endothelial cells of the splenic sinuses. Others have failed to find this phenomenon. It is extremely difficult to study phagocytosis of platelets in paraffin sections. The study of smears from the splenic vein at time of operation and imprints of the spleen before fixation would be a distinct aid in this direction. One can conclude that the spleen shows no gross or microscopic changes which are characteristic of thrombocytopenic purpura.

In recent years, the value of bone marrow studies in essential thrombocytopenic purpura has been widely recognized. Post-mortem autolysis and embalming usually restrict bone marrow studies at autopsy to paraffin sections of fixed and decalcified material. Hence, one is at a disadvantage in studying minute cellular detail as compared to fresh material in the living patient stained with some modification of the Romanowsky stain. Unfortunately in these thirty-six patients, the bone marrow was examined in only ten. Sections

were available for study in eight of the ten. In the patients not available for study, the bone marrow was described as negative for leukemia and normal megakaryocytes. In the remaining eight, three died following splenectomy. These three patients showed a marked reduction in the number of megakaryocytes in the marrow. We are rapidly beginning to realize that in any patient with thrombocytopenic purpura, where the marrow shows a marked decrease in number of megakaryocytes, the patient is likely to receive little benefit from a splenectomy. This is well illustrated by the following case in this series.

A woman, 22 years of age, gave a history of bleeding from gums, vagina, and skin purpura beginning in February of 1942. Red blood count on admission to the hospital was 1,260,000 cells per cubic millimeter; hemoglobin, 33 per cent (Sahli); leukocyte count, 7,700 cells per cubic millimeter with 69 per cent neutrophils; platelet count, 55,000 per cubic millimeter; bleeding time, over 16 minutes; and coagulation time, 4 minutes. Three bone marrow aspirations showed an absence of megakaryocytes and no evidence of leukemia. The patient was given six blood transfusions. On Feb. 28, 1942, a splenectomy was done as a possible lifesaving procedure. The platelet count rose but declined on the second post-operative day with a return of purpuric bleeding. The patient died on the fifth post-operative day from generalized purpura. The bone marrow at autopsy showed an absence of megakaryocytes.

The bone marrow in the five patients not operated upon showed a marked increase in the number of megakaryocytes with the presence of many immature megakaryocytes. Every high power microscopic field had from one to several large megakaryocytes. The degree of platelet production on the part of megakaryocytes could not be determined in the fixed tissue. These marrows otherwise appeared relatively normal except for a compensatory normoblastic erythroid hyperplasia and myeloid hyperplasia compatible with a chronic bleeding state. Eosinophilia was not noted. The question arises as to whether one should restrict the definition of essential thrombocytopenic purpura to only those cases that show a marked increase in number of megakaryocytes in the bone marrow together with the presence of immature megakaryocytes. However, some investigators, as Rosenthal,⁷ refer to one type of idiopathic thrombocytopenic purpura where megakaryocytes are reduced in number. One would expect poor results from splenectomies in these cases.

We are still ignorant as to the nature of the capillary defect and relationship of the spleen, platelets, and capillaries in this disease. The large numbers of megakaryocytes in the bone marrow would tend to show, as emphasized by Limarzi and Schleicher⁸ and Dameshek and Miller,⁹ that the lack of platelets is the result of a splenic depressing factor that interferes with the proper maturation of the megakaryocytes in the bone marrow.

CONCLUSIONS

1. The post-mortem findings of thirty-six patients with essential thrombocytopenic purpura are recorded.
2. The average weight of the spleen in twenty adults was 232 grams. There were no characteristic histologic findings.
3. Apart from the widespread hemorrhages, the presence of increased number of megakaryocytes in the bone marrow is the most constant post-mortem finding in essential thrombocytopenic purpura.

EXPERIENCE WITH PTEROYLGLUTAMIC (SYNTHETIC FOLIC) ACID IN THE TREATMENT OF PERNICIOUS ANEMIA

BYRON E. HALL, M.D., AND CHARLES H. WATKINS, M.D.
ROCHESTER, MINN.

THE synthesis of a compound known to have a specific stimulating effect on hematopoiesis in man and in certain laboratory animals was announced in August, 1945, by a group of sixteen investigators.¹ This substance, synthetic folie acid, was found to be identical with the *Lactobacillus casei* factor previously derived in pure form from liver.² Extracts containing a substance or substances essential to the growth of *Lactobacillus casei* (and *Streptococcus lactis R*) have been obtained from sources³⁻⁶ other than liver, namely, kidney, yeast, and the green leaves of many plants, notably spinach. As yet it is not known, however, whether the active principle in these extracts is identical with the synthetic compound or with the factor derived from liver.⁶ Spies and associates⁷ considered synthetic folie acid to be a part of the vitamin B complex. The formula and the method of synthesis of the hepatic *L. casei* factor were published in May, 1946; "pteroylglutamic acid" was suggested as a name for this compound.⁸

In recent months reports have been published on the therapeutic effectiveness of pteroylglutamic (synthetic folie) acid in certain macrocytic anemias. The rationale of use of this substance in the treatment of anemias of the macrocytic type was based on the experimental work of Wills and associates^{9, 10} in England and of Day and co-workers¹¹⁻¹⁴ in this country. These workers produced a dietary deficiency in monkeys characterized by macrocytic anemia, leukopenia, diarrhea, and oral lesions (necrosis and ulceration of the gums), a syndrome not unlike that of sprue in man. Day and co-workers postulated that the deficiency was due to an unknown substance for which the term "vitamin M" was proposed. Subsequently, the same group of investigators demonstrated that deficiency of vitamin M in monkeys could be treated successfully with a highly purified *L. casei* factor.^{14, 15}

The similarities of the sprue syndrome in man to the manifestations of deficiency of vitamin M in monkeys led two groups of investigators, Spies and associates and Darby and co-workers, to study the effect of the synthetic compound in patients with sprue.^{7, 16-22} Clinical improvement characterized by disappearance of the glossitis, regeneration of lingual papillae, subsidence of diarrhea, and gain in weight was noted. Concurrently, a marked hematologic response manifested by reticulocytosis and a rise in values for hemoglobin and erythrocytes was observed.

Studies on the therapeutic value of pteroylglutamic acid in other types of macrocytic anemia—addisonian pernicious anemia, pernicious anemia of pregnancy, nutritional macrocytic anemia, and macrocytic anemia of infancy—now have been reported also.^{7, 19, 23-25} Vilter and associates¹⁶ and Moore and co-

From the Division of Medicine, Mayo Clinic.

Read before the Minnesota Society of Internal Medicine, Oct. 21, 1946.

The pteroylglutamic (synthetic folie) acid employed in this study was furnished by Dr. Stanton M. Hardy, of the Lederle Laboratories, Inc., Pearl River, N. Y.

*Reference to vitamin B₁₂ and allied substances has been omitted, since evidence indicates that, although related, they probably are not identical with pteroylglutamic acid. The physiologic action of vitamin B₁₂ on hematopoiesis, however, appears to be similar to that of pteroylglutamic acid.

workers²³ reported simultaneously in December, 1945, on the effect of pteroylglutamic acid in Addisonian pernicious anemia in relapse. To the results observed in the seven cases reported by these investigators, Doan and associates^{24, 26} have added their observations in four cases, Kaufmann and Schwager²⁷ in two cases, Amill and Wright²⁸ in six cases, and Goldsmith²⁹ in four cases, making a total of twenty-three cases of pernicious anemia in relapse on which published data concerning the effects of pteroylglutamic acid therapy are available. In these twenty-three cases the administration of pteroylglutamic acid, orally or parenterally, resulted in a reticulocyte response, an increase in values for hemoglobin and erythrocytes, and clinical improvement. Although studies on the effects of this form of therapy on the bone marrow of patients who had pernicious anemia in relapse have been made in several of the reported cases, detailed studies are available in only two instances.^{24, 26} In these cases the megaloblastic marrow of pernicious anemia in relapse was converted to a marrow which approaches normal from the tenth to the fourteenth day of treatment.

It is the purpose of this paper to record our observations on the effects of pteroylglutamic acid therapy in fourteen patients with classical Addisonian pernicious anemia in relapse. We wish to emphasize particularly the changes observed in the bone marrow after the administration of this substance and the failure of the synthetic compound to relieve or prevent the development of gastrointestinal and neurologic manifestations of the disease.

MATERIAL AND METHODS

In nine of the fourteen cases included in this study the condition in question was seen for the first time, the diagnosis having been made just prior to treatment with pteroylglutamic acid. In the remaining five cases (Patients 1, 2, 3, 7, and 14) a sensitivity to liver extracts previously administered parenterally had developed in two (Patients 7 and 14), and the patients were in severe relapse at the time of their admission to the Mayo Clinic. Two others (Patients 2 and 3) in this group of five had been informed one year and three years previously that they had pernicious anemia, but they had neglected liver therapy over periods of many months. The fifth (Patient 1) had received a single intramuscular injection of liver extract one week before admission because his physician told him that he was anemic, although the diagnosis of pernicious anemia apparently had not been established. Eight of the fourteen patients were women and six were men. Their ages ranged from 48 to 72 years. Six of the fourteen patients were hospitalized during the first four to six weeks of treatment and were given a routine hospital diet. The remaining eight patients were seen daily or every second day in the clinic and were maintained on diets of an average protein content (70 Gm.).

During the first two weeks of treatment erythrocyte and reticulocyte counts were made daily; subsequently, such counts were made every second or third day. Reticulocyte percentages were obtained by counting 1,000 cells on dry films stained with brilliant cresyl blue and counterstained with Wright's stain (Grübler). The Sheard-Sanford photometer was used for the determination of values for hemoglobin, and a Haden erythrocytometer was employed for the determination of average erythrocyte diameters. Sternal puncture was performed in twelve of the fourteen cases prior to the institution of therapy and was repeated at intervals in each case, so that in the aggregate at least one puncture was performed for each day from the second to the tenth day of treatment. Both the oral route and the parenteral route of administration of pteroylglutamic acid were employed.

RESULTS

Hematologic Response.—The quantity of pteroylglutamic acid administered, the route of administration, and the hematologic response in respect to

each of the fourteen patients is shown in Table I. Peaks of the increase in reticulocytes occurred from the fifth to the fourteenth day after the institution of therapy, and the increases varied from 1.6 to 17.6 per cent. These values, in general, are somewhat lower than those reported by other observers and are less than the reticulocyte peaks observed after liver therapy among patients who had pernicious anemia in similar states of relapse.

Although treatment with pteroylglutamic acid resulted in an increase in values for erythrocytes and hemoglobin in all cases, the rapidity of the increase was variable. In some cases the response appeared to be as rapid as that usually observed with liver therapy (Fig. 1), but in other cases it was decidedly delayed (Fig. 2). In three patients the values for erythrocytes did not increase above 3,500,000 cells per cubic millimeter of blood, despite daily doses of 15 to 20 mg. over periods as long as eleven weeks (Patients 2, 9, and 13). In these three patients normal blood values subsequently were induced with liver therapy. Recession in the degree of macrocytosis occurred in all cases, but a return to essentially normal cell diameters was observed in only three instances (Patients 4, 11, and 14).

Leukocyte counts of less than 5,000 cells per cubic millimeter were observed in six of the fourteen patients prior to treatment with pteroylglutamic acid. Treatment resulted in an increase in the number of leukocytes to normal in two cases (Patients 1 and 7), an increase with persistence of a subnormal value in two (Patients 8 and 14), and a decrease in two (Patients 2 and 12). Platelet determinations made prior to treatment with pteroylglutamic acid revealed thrombocytopenia in four of seven patients. After treatment, an increase in platelet values occurred in all four patients.

In the twelve patients for whom sternal puncture was performed megaloblastic regeneration in the bone marrow was found prior to treatment with folic acid. Treatment resulted in a rapid conversion to a normoblastic marrow, the conversion being essentially complete in seven to ten days. The changes observed are illustrated in material aspirated serially in a typical instance (Figs. 3 to 5).

Clinical Observations.—Although evaluation of subjective symptoms is more difficult than analysis of objective data, the impression was gained that in pernicious anemia in relapse treatment with pteroylglutamic acid resulted in less pronounced and less rapid subjective improvement than that commonly observed after the institution of liver therapy. With the exception of two cases in which the hematologic response to pteroylglutamic acid therapy was rapid, weakness persisted longer and the restoration of a sense of well-being, which often occurs with startling rapidity after the administration of liver extract, either was significantly delayed or did not occur.

The results of treatment with pteroylglutamic acid over periods of many months on the glossitis and neural manifestations of pernicious anemia are summarized in Table II. Of seven patients who had glossitis, six improved under treatment; however, the improvement of four of these was slower than that observed with liver therapy, since one to three and a half months of therapy with acid were required for restoration of a normal tongue. Three of the six patients experienced recurrence of glossitis at a later date; in two of them (Patients 2 and 7) satisfactory hematologic remission was not induced, but in

Fig. 1.—A satisfactory erythrocytic response (Patient 14) to pteroylglutamic acid therapy in pernicious anemia in relapse. The increase in values for erythrocytes and hemoglobin was rapid, and the reticulocyte response appeared to be either maximal or very nearly maximal.

Fig. 2.—An unsatisfactory erythrocytic response (Patient 13) to pteroylglutamic acid therapy in pernicious anemia in relapse. Only a slight increase in the number of erythrocytes occurred over the first four days. The initial submaximal reticulocyte response may have been caused by the small dose administered during the first eleven days of treatment. Larger doses both orally and parenterally did not result in a significant regeneration of erythrocytes. Therapy with liver extract administered brought about restitution of normal blood values.

Fig. 3a and b.—Specimens of sternal bone marrow aspirated serially in a patient with Addisonian pernicious anemia (Patient 2), during relapse before treatment with pteroylglutamic acid, depicting a predominance of promegaloblasts and basophilic megaloblasts ($\times 650$).

Fig. 4a and b.—a, Same case as concerned in Fig. 3. Specimen of sternal marrow three days after the institution of pteroylglutamic acid therapy, showing late megaloblastic maturation, manifested by a predominance of orthochromatic megaloblasts ($\times 650$); b, normoblastic regeneration in same specimen as shown in Fig. 4a, as evidenced by basophilic, polychromatic, and orthochromatic normoblasts ($\times 650$).

the third (Patient 8) the blood picture was essentially normal at the time of recurrence of the glossitis except for persistence of a slight degree of macrocytosis. The one (Patient 9) who obtained no abatement of the glossitis was treated with pteroylglutamic acid for only twenty-four days. Although therapy apparently failed in this instance, the period of observation was too short to permit the formation of conclusions.

Fig. 5a and b.—a, Same case as concerned in Figs. 3 and 4, showing specimen of sternal bone marrow eight days after institution of pteroylglutamic acid therapy, depicting active normoblastic regeneration: a few scattered megaloblasts could still be found at this stage ($\times 650$); b, specimen of sternal marrow thirty-four days after the institution of pteroylglutamic acid therapy, showing resumption of active myelopoiesis as well as less intensive normoblastic regeneration ($\times 650$).

Of the ten patients who had paresthesia in the extremities, eight improved, but the improvement of four patients was temporary. It is of interest that paresthesia recurred within two to four months after the institution of therapy, at a time when three of the four patients no longer were anemic (Patients 4, 5, and 6). Of later interest is the observation that in two patients

†Short period of observation.

who had not had paresthesia prior to treatment, this symptom developed five months after treatment had been started (Patients 3 and 6).

The condition of two patients who had peripheral neuropathy and early signs of subacute combined degeneration of the spinal cord (Patients 1 and 10) did not improve during five or six weeks of treatment. The size of the dose of pteroylglutamic acid administered to one of these patients was five times greater (100 mg. daily) than that administered to the other, but during the short period the patient receiving the larger dose was under observation before treatment with liver extract was begun, the neural manifestations of the disease were not altered. Of particular significance was the development of early but definite signs of subacute combined degeneration of the spinal cord in three patients who had not had involvement of the central nervous system prior to treatment with pteroylglutamic acid (Patients 3, 7, and 8). Two, however, had paresthesia in the extremities which abated temporarily after treatment and then recurred two to four months later. Signs of involvement of the spinal cord in these cases were loss of sense of vibration and sense of position in the lower limbs, slight incoordination, presence of the Romberg sign, slight but definite ataxia, and, in one patient, the bilateral presence of the Babinski great toe sign. The neural manifestations developed within two to five months after treatment with pteroylglutamic acid had begun. In one case (Patient 8) they developed at a time when the number of erythrocytes was normal, although a slight degree of macrocytosis persisted. In another (Patient 3), in which the patient who had not had symptoms or signs of involvement of the nervous system prior to treatment with pteroylglutamic acid, a satisfactory hematologic remission was not induced, as manifested by persistence of macrocytosis and a value for erythrocytes that did not increase above 4,000,000 cells per cubic millimeter of blood, except on one occasion. One case (Patient 7) is of special interest because the erythrocyte count increased from 1,150,500 to 4,000,000 cells per cubic millimeter over a period of four months and then decreased to 3,210,000 cells per cubic millimeter in the next five weeks (Fig. 6). During the period of decrease in number of erythrocytes and with the patient receiving a daily maintenance dose of 15 mg. of pteroylglutamic acid by mouth, glossitis and paresthesia in the extremities recurred and signs of subacute combined degeneration of the spinal cord developed. Inquiry into the diets of three patients revealed essentially normal diets in two (Patients 3 and 8), but the

diet in one (Patient 7) was low in protein. In the latter instance the patient estimated that she had not received in excess of a half pound of animal protein weekly for a period of two months prior to the development of glossitis and the symptoms of involvement of the nervous system. She attributed the low intake of protein to the meat shortage prevailing during the summer of 1946.

Fig. 6.—Diminution of the number of erythrocytes per cubic millimeter of blood in a patient with pernicious anemia receiving orally a daily dose of 15 mg. of pteroylglutamic acid, after an apparently satisfactory initial response to such therapy. In this case (Patient 7) relapse was due to cessation of liver therapy, many months prior to the patient's admission, because of sensitivity to liver extracts. The presenting symptoms were glossitis and paresthesia in the lower extremities, but the signs of combined systemic disease were absent. During the first two months of treatment the glossitis and paresthesia abated but then recurred and became moderately severe during the last few weeks of treatment. During the period of the decrease in erythrocytes, the early signs of subacute combined degeneration of the spinal cord developed. Desensitization of the patient to liver extract administered parenterally then was carried out, and intensive liver therapy subsequently resulted in restitution or normal blood values and symptomatic improvement.

COMMENT

Pteroylglutamic acid appears to be an essential nutrient for man, for various laboratory animals, and for certain microorganisms. An important physiologic property is the stimulating effect of the acid on hematopoiesis, which is most pronounced in certain, but not all, types of macrocytic anemia in man characterized by megaloblastic regeneration in the bone marrow. In this type of anemia, including addisonian pernicious anemia, the administration of the

synthetic compound results in the prompt conversion of a pathologic megaloblastic form of erythropoiesis to a normal normoblastic form of erythropoiesis. Concomitant with the changes observed in the bone marrow, a hematologic response occurs, characterized by reticulocytosis and an increase in values for hemoglobin and erythrocytes. An increase in the number of leukocytes and platelets also occurs in most cases in which leukopenia and thrombocytopenia are found prior to treatment.

Although the foregoing remarks on the hematopoietic-stimulating effect of pteroylglutamic acid applied, in general, to all cases of patients with pernicious anemia in our series, considerable variation in the rate of hematologic improvement occurred. Only three of fourteen patients who had pernicious anemia in relapse treated with pteroylglutamic acid showed an erythrocyte response comparable to that which occurs after liver therapy. In the remaining eleven cases the rate of increase of erythrocytes was significantly slower than the expected response to treatment with liver extract. In four cases normal values for erythrocytes were not attained after eight to ten weeks of treatment. Subsequent intensive liver therapy, however, resulted in the restitution of normal blood values in these four cases. It is of interest to note also that in the majority of our cases the reticulocyte responses to treatment with pteroylglutamic acid were lower than the standard maximal reticulocyte responses that have been established for various erythrocyte levels after the intramuscular administration of liver extract.³⁰⁻³²

Clinical improvement after pteroylglutamic acid therapy, as well as the hematologic response, was found to be variable in patients who had pernicious anemia in relapse, and often it was slower than the response observed with liver therapy. In a significant proportion of cases glossitis and neurologic manifestations of the disease either failed to abate or recurred after temporary abatement. Of greater significance was the development of signs of subacute combined degeneration of the spinal cord in three of the fourteen patients treated with pteroylglutamic acid in doses of 10.0 to 15.0 mg. administered daily by mouth for periods of two to five months.* These observations suggest that the physiologic action of pteroylglutamic acid on the alimentary tract and nervous system in pernicious anemia is not identical with that of the antipernicious anemia factor contained in liver, even though the action on the bone marrow is similar.

Although pteroylglutamic acid has antianemic properties, it is probable that this factor and the antipernicious anemia factor contained in liver are not the same. The quantity of pteroylglutamic acid contained in liver extracts is small. Clark³³ reported that various commercial liver extracts contain 0.25 to 0.5 micrograms of the *L. casei* factor per U.S.P. unit. Thus, a patient receiving 150 units of the antipernicious anemia factor in liver extract (10 c.e.) during the first ten days of treatment would receive only 5.5 micrograms of pteroylglutamic acid. Doses required for hemopoietic response are considerably larger. In our study the minimal amount of pteroylglutamic acid administered

*Since this paper was written, Vilter, Vilter, and Spies, at the annual meeting of the Central Society of Clinical Pharmacology, N. Y., 1946, reported the development of combined systemic disease in four patients with pernicious anemia after five to eight months of treatment with pteroylglutamic acid. The administration of 50 to 500 mg. of the *L. casei* factor for ten to forty days did not result in subjective or objective improvement. We have learned also, in a personal communication, that L. Meyer of New York City previously had reported similar observations.

to the patient during the first ten days of treatment was 50,000 micrograms. However, hemopoietic responses have been obtained with as little as 20,000 micrograms during the first ten days of therapy.²⁴

It is obvious that the discovery and synthesis of pteroylglutamic acid are important advances in the fields of nutrition and hematology. The observation that this substance does not prevent the development of glossitis and neural manifestations in pernicious anemia, even after the induction of hematologic remission, in no way detracts from the significance of the demonstration that deficiency of a substance of known chemical composition profoundly inhibits erythrocytic maturation, and possibly the maturation of other elements, in the bone marrow. Although present evidence indicates that pteroylglutamic acid should not be employed as a form of replacement or substitution therapy in pernicious anemia, whether in relapse or remission, data concerning the usefulness of this agent in the treatment of other types of macrocytic anemia related to pernicious anemia are accumulating rapidly. In our experience pteroylglutamic acid therapy has been found to be particularly effective in the treatment of nutritional macrocytic anemia and macrocytic anemia of infancy.

SUMMARY AND CONCLUSIONS

Fourteen patients who had addisonian pernicious anemia in relapse were treated with pteroylglutamic (synthetic folie) acid over periods from twenty-four days to nine months. The most striking effect of this form of therapy was observed in the bone marrow, erythropoiesis rapidly changing from a megaloblastic to a normoblastic type. However, considerable variation in the rate of erythrocytic regeneration was encountered, and in certain instances normal blood values were not obtained after several months of treatment with pteroylglutamic acid in doses generally thought to be relatively large.

Symptomatic improvement also was variable. Treatment resulted in abatement of glossitis and peripheral neuropathy in most cases, but recurrence was common among persons maintained solely on this form of therapy for a period of months. Moreover, peripheral neuropathy and subacute combined degeneration of the spinal cord developed as new manifestations in a significant proportion of cases two to five months after treatment was begun. In the light of these observations it is obvious that pteroylglutamic acid does not prevent the occurrence of degenerative disease of the peripheral nerves and spinal cord in pernicious anemia and that the use of this form of therapy as a substitute for extracts of liver or gastric mucosa subjects patients to the hazards of progression or development of the neural manifestations of the disease. On the other hand, pteroylglutamic acid has been found to be an effective therapeutic agent in certain macrocytic anemias related to pernicious anemia, a subject not considered in the present paper.

THE EFFECT OF SYNTHETIC LACTOBACILLUS CASEI FACTOR ON THE BLOOD CHANGES INDUCED BY GASTRECTOMY IN THE RAT

GEORGE M. HIGGINS, PH.D.,* ROCHESTER, MINN., DWIGHT J. INGLE, PH.D.,†
KALAMAZOO, MICH., AND OLIVE R. JONESON,‡ ROCHESTER, MINN.

ONE of the newest members of the group of water-soluble B vitamins is folic acid (synthetic *Lactobacillus casei* factor). The recognition of its function in the animal organism and its final synthesis¹ were the result of widely independent investigations in several laboratories extending over a period of fifteen years or more. Factors found essential for the growth of microorganisms (*L. casei* and *Streptococcus lactis R*) and factors found essential for the nutrition of the chick (B_c) and of the monkey (vitamin M) may prove to have common physiologic significance.

Snell and Peterson² in 1940 found that a yeast extract and a solubilized liver fraction were good sources of a growth factor essential for *L. casei*. Mitchell and associates³ in 1941 first used the term "folic acid" to describe a factor which they obtained from spinach and which is essential for the growth of *Str. lactis R*. Liver, yeast, and other substances proved to be rich sources of this factor. Hogan and Parrott⁴ in 1939 used the term "vitamin B_c " to designate a dietary factor, obtained from a water-soluble extract of liver, which prevented macrocytic hyperchromic anemia in chicks. Pfaffner and co-workers⁵ in 1943 isolated a crystalline compound from liver, and Campbell and associates⁶ in 1944 showed that this compound would prevent nutritional macrocytic anemia in chicks. The designation of Hogan and Parrott (vitamin B_c) was retained. The term "vitamin M" was employed by Day and associates⁷ in 1938 to designate that factor in yeast and in liver which protected monkeys from fatal dietary cytopenia. In 1945 Day and co-workers⁸ expressed the belief that *L. casei* factor is identical with vitamin M.

On the recognition that substances so widely scattered in nature are essential growth factors and possess antianemic potencies, numerous reports of the influence of liver and yeast concentrates, known to contain *L. casei* factor, were reported. Experimental anemia was induced in various ways. Spicer and associates⁹ in 1942 reported that the leukopenia induced in rats by sulfonamide drugs could be prevented with liver extracts containing this factor. Kornberg and associates¹⁰ in 1943 were able to correct severe granulocytopenia. By means of a folic acid concentrate Ransone and Elvehjem¹¹ in 1943 increased the leukocyte production in rats given sulfasuxidine. Likewise, Axelrod and co-workers¹² in 1943 corrected experimental leukopenia with a norite eluate factor or with whole liver. Higgins¹³ in 1944 reported that a vitamin B_c concentrate had a marked antianemic effect on rats given promin.

After the isolation of vitamin B₁₂ by Pfaffner and associates⁵ in 1943 and of the *L. casei* factor by Hutchings and co-workers¹⁴ in 1944, additional studies using purified products were reported. Using crystalline folic acid, Daft and Sebrell¹⁵ in 1943 reported the correction of experimental granulocytopenia. Mallory and associates¹⁶ in 1944 increased granulocyte percentages in rats made leukopenic with succinylsulfathiazole. Spontaneous granulocytopenia observed in a small percentage of rats fed purified diets was corrected by the *L. casei* factor (Kornberg and co-workers¹⁷ in 1945). Likewise, *L. casei* factor was found by Kornberg and co-workers¹⁸ in 1944 to have a preventive as well as corrective action on induced hemorrhagic anemia. Granulocytopenia induced by thiourea, when thyroxin or powdered thyroid was given simultaneously, was found by Daft and associates¹⁹ in 1946 to be corrected by crystalline *L. casei* factor. But neutropenia induced by the injection of benzol, a bone marrow depressant, was not corrected by folic acid, according to Platt and co-workers²⁰ in 1946. The neutropenia following administration of sulfonamide compounds was considered to be due to a decrease of the number of coliform organisms which presumably synthesize the *L. casei* factor in the lower part of the intestinal tract. Exogenous folic acid thus was able to correct the induced neutropenia.

The extensive literature covering the reports of studies on the effects of *L. casei* factor on various cases of clinical anemia was reviewed by Berry and Spies²¹ in 1946. Synthetic *L. casei* factor appeared to exert striking antianemic effects on the several types of macrocytic anemia and was found effective in inducing remissions in some cases of pernicious anemia. Goldsmith,²² reporting late in 1946 her study of five patients who had severe anemia, stated that there was improvement in their physical condition as well as in their hematologic status on the administration of *L. casei* factor. Bethell and collaborators²³ in 1946 stated that therapeutic effects were not obtained when the B₁₂ conjugate was given to a gastrectomized patient, but an equivalent amount of folic acid incited a significant hematologic response.

Experimental gastrectomy has been shown to induce marked hematologic changes in some species of animals. The literature is extensive, and space does not permit a comprehensive review of the available reports. Briefly, the total removal of the stomach from rats (Jung,²⁴ 1933; Maisson and associates,²⁵ 1933; Bussabarger and Jung,²⁶ 1936; and Ivy,²⁷ 1940) induced changes of body weight and severe hematologic changes including marked microcytosis. Large amounts of ferric ammonium citrate did not alter the weight curve but did improve the blood picture strikingly. A complete return to normal levels was difficult to attain with iron alone, but the administration of a concentrate of a liver protein with iron was reported to correct the hematologic dyscrasia. It was obvious that the stomach is an essential organ for the maintenance of health in the rat, but blood findings in any way resembling those of pernicious anemia did not ensue on its removal.

Since synthetic *L. casei* factor has been shown to be corrective for certain clinical anemias, and since it has been shown to be effective in controlling cer-

tain nutritional anemias and other experimental anemias thought to be induced by altering intestinal flora by various drugs, a study was made of its effectiveness in correcting the blood changes incident to the removal of the stomach.

EXPERIMENTAL PROCEDURES

Healthy adult male rats of the Sprague-Dawley strain were selected. Gastrectomy was performed with the rats under ether anesthesia, the esophagus being joined to the duodenum by an end-to-side anastomosis. Sixteen animals were gastrectomized; eight were not submitted to operation and served as the control group. All animals, both control and test, were provided a purified diet consisting of 64 per cent sucrose, 24 per cent vitamin-free casein (Labco brand), 6 per cent corn oil, 2 per cent cod-liver oil, and a 4 per cent salt mixture No. 2, U.S.P. XII. Adequate amounts of thiamine, riboflavin, pyridoxine, niacin, calcium pantothenate, choline, inositol, and para-amino-benzoic acid were supplied. Water was provided ad libitum. All animals were maintained in metal cages, on metal screen three mesh to an inch, three animals to a cage. The average food intake was recorded daily for three two-week periods: immediately after operation, two months after operation, and seven months after operation. Animals were weighed at intervals of two weeks.

Samples of blood, always obtained from the hearts of both control and test animals, were examined at three weeks, six weeks, three months, and five months after gastrectomy. Shortly after the five-month sampling, 200 micrograms of synthetic *L. casei* factor* were given to each control and test animal by stomach tube. Seventy-two hours later the blood was again examined and data were assembled.

Two weeks later when the effects of the previous administration were presumably gone, the animals were fed the purified diet to which *L. casei* factor was added at a level of 100 micrograms per gram. After fourteen days on this dietary regimen the blood was again sampled and the data were assembled.

The purified diet, without the *L. casei* supplement, was again provided to the animals. After an interval of time sufficient to free the animals of the orally administered vitamin, all gastrectomized rats were given, each day for fourteen days, 400 micrograms of *L. casei* factor, intraperitoneally. At the end of this time the blood was again sampled and corresponding data were assembled.

RESULTS

All animals withstood the immediate postoperative period reasonably well. Three died of obstruction at the site of the anastomosis within the first two weeks. Three died as a result of hemopericardium occasioned by heart puncture, and four died during the summer for reasons presumably unrelated to the study. In cases of obstruction an abscess usually developed at the site of anastomosis, and the body weight of the animal dropped rapidly. Only the six gastrectomized animals which survived the initial five-month period and were without obvious pathologic defects were used in the computation of the following data.

A. Food Intake.—In the initial period, soon after gastrectomy, control animals ate on the average 15.1 Gm. (63.4 calories) of the diet per day, while the gastrectomized animals took 12.7 Gm. (52.3 calories) per day. Two months later, the nongastrectomized control animals were eating 10.7 Gm. (44.9 calories), while the gastrectomized animals were eating approximately an equal amount, 10.3 Gm. (43.2 calories) per day. This period of measuring the food intake was in midsummer, and it is our belief that the decline in the amount

*The pteroylglutamic (synthetic folic) acid employed in this study was furnished by Dr. Stanton M. Hardy of the Lederle Laboratories, Inc., Pearl River, N. Y.

consumed by the controls may have been owing to the higher temperatures and to the increased humidity levels of the season. Seven months after the operation, the control animals were eating on the average 11.7 Gm. (49.1 calories), while the gastrectomized animals were taking 8.9 Gm. (37.4 calories) daily. Although the food intake appeared to be quite satisfactory, only slightly less being consumed by the gastrectomized animals than by their controls; yet, the gastrectomized animals appeared undernourished, their coats were rough and unkempt, and all showed marked evidence of nutritional deficiencies.

B. Body Weights.—The average weight of the eight nongastrectomized control animals at the beginning of the experiment was 320 grams; that of the sixteen gastrectomized animals, constituting the test group, was 310 grams. The body weight data of the test group given in Table I were obtained from the six gastrectomized animals which had survived for five months and which were continuously free of any obvious pathologic defect.

TABLE I. BODY WEIGHTS IN GRAMS

	CONTROL	TEST
Preoperative	320	310
Postoperative		
One week	337	296
Two weeks	352	305
One month	364	318
Two months	380	324
Five months	372	236
Seven months	335	207

It is obvious from these data that the gastrectomized animals lost weight for a brief period and then increased it slightly for two months after the operation. Their weight then fell rapidly, a third of their preoperative weight having been lost at seven months. This loss may be owing to the fact that their food intake at this period was also nearly a third less than the amounts consumed daily during the early period after gastrectomy.

C. Effect on the Blood of a Single Oral Administration of Synthetic L. Casei Factor.—Data assembled from the heart bloods of normal and gastrectomized rats, five months after operation, before, and seventy-two hours after giving 200 micrograms of *L. casei* factor by mouth are condensed in Tables II

*Probable error of the mean.

and III. Healthy gastrectomized animals never had low total erythrocyte counts. The mean of the data obtained from thirteen animals three weeks after operation was $8,550,000 \pm 200,000$ cells per cubic millimeter of blood. At that time their erythrocyte volumes and their hemoglobin levels did not differ from those values found in the nongastrectomized control animals. At five months, however, there was significant microcytosis and the amount of hemoglobin in grams per 100 c.c. of blood was greatly reduced.

A single administration of *L. casei* factor was without significant effect on the total erythrocyte count, the erythrocyte volumes, the grams of hemoglobin, or the total leukocyte count. Slightly significant elevations, however, were obtained in the reticulocyte percentages. In the data on leukocytes we observed some increase of the percentages of myelocytes in the blood of both control and test animals, but the total number of neutrophilic leukocytes was not increased. The conclusion was indicated that a single oral administration of the factor, in the amounts given, was without significant effect on the blood, seventy-two hours later.

D. Effect on the Blood of Including Synthetic L. Casei Factor in the Diet, at a Level of 100 Micrograms Per Gram.—Data assembled before placing animals on the diet, supplemented by *L. casei* factor, and those assembled after feeding this diet for two weeks are condensed in Tables IV and V. Although control animals took an average of 1,160 micrograms of the factor daily and test animals took an average of 920 micrograms daily, significant changes were not observed in the total number of erythrocytes per cubic millimeter, the volumes of erythrocytes, or the hemoglobin levels in gastrectomized animals. Again, there was a significant increase in the reticulocyte percentages in the test series. Although the percentage of lymphocytes in the blood of test animals dropped from 61.6 to 30.7, the total number of lymphocytes remained unchanged as a result of taking large amounts of the factor for fourteen days.

A marked increase, however, occurred in the percentage and in the total number of immature and mature neutrophilic granulocytes. These increments

				MYELO- CYTES	META- MYELO- CYTES		MATURE
21.6 + 2.1	0.2	2.0 ± 0.1	0	22.6 ± 3.4	7.0 ± 1.0	46.6 ± 4.4	11.1 ± 1.1

*Probable error of the mean.

were more marked in test animals than in the controls. Percentages of myelocytes increased from 3.4 to 10.0; of metamyelocytes, from 1.2 to 4.0; and of mature granulocytes, from 33.0 to 53.7. Thus, as a result of providing the *L. casei* factor in the diet for fourteen days, myeloid stimulation produced an absolute increase of total circulating neutrophilic granulocytes from 1,900 to 7,200 per cubic millimeter of blood.

E. Effect on the Blood of Gastrectomized Rats of Injecting 400 Micrograms of Synthetic L. Casei Factor Intraperitoneally Daily for Fourteen Days.— Since we wished to avoid the risk of losing valuable animals, data on the blood were not assembled prior to the intraperitoneal injections of *L. casei* factor. Two weeks had elapsed, however, since the conclusion of the preceding experiment; so that we had reason to believe that the blood picture had reverted to levels previously recorded. The data assembled after fourteen daily injections are condensed in Table VI.

Parenteral administration of the factor was without effect on the total erythrocyte count, the size of erythrocytes, or the grams of hemoglobin per 100 c.c. of blood. There was a slightly greater increase in the percentage of reticulocytes and a considerably greater increase in the total number of leukocytes than occurred when more than twice the amount of the factor was taken with the diet for the same length of time. Again, the total number of lymphocytes per cubic millimeter of blood remained unchanged as a result of these daily injections. However, the percentages of myelocytes and metamyelocytes were both significantly higher, and the total number of neutrophilic granulocytes per cubic millimeter of blood increased from the previous level of 1,900 to 11,100.

It seems obvious from our data that neither the oral nor the parenteral administration of synthetic *L. casei* factor to gastrectomized rats produced a significant effect on the total erythrocyte count, the volumes of erythrocytes, or the grams of hemoglobin per 100 c.c. of blood. It had a decided effect, however, on the myeloid series of leukocytes and its prolonged administration (two weeks) either parenterally or orally resulted in a marked increase of the numbers of immature and mature neutrophilic granulocytes in the circulating blood.

SUMMARY

A study is reported of the effects on the blood changes induced by gastrectomy in white rats, of giving synthetic *L. casei* factor. Sixteen adult male rats were gastrectomized. Of these, six survived for five months and were used as test animals. All were without obvious signs of any gross pathologic changes, as a result of the surgical intervention, but all showed evidence of malnutrition, manifested by progressive loss of weight, and by their rough and discolored coats. Eight nongastrectomized rats served as controls.

Five months after gastrectomy, the total erythrocyte counts were normal, the hemoglobin levels were reduced, and marked microcytosis had developed. Seventy-two hours after a single administration of synthetic *L. casei* factor (200 micrograms), a slight but significant elevation of the percentage of reticulocytes was obtained, but there were no changes in the total erythrocyte counts, the volumes of erythrocytes, the hemoglobin levels, or the total leukocyte counts.

When *L. casei* factor was added to the purified diet, at a level of 100 micrograms per gram, and fed to gastrectomized rats for fourteen days, changes did not occur in the total numbers of erythrocytes, the volumes of erythrocytes, or the levels of hemoglobin. Slightly significant increases occurred in the percentages of reticulocytes and markedly significant increases occurred in the total numbers of leukocytes. This increase of the number of leukocytes was due entirely to a myeloid stimulation, for the numbers of lymphocytes remained unchanged. There was a marked increase of the total number of circulating myelocytes, metamyelocytes, and mature neutrophilic granulocytes.

When *L. casei* factor was injected intraperitoneally daily for fourteen days in amounts equivalent to 400 micrograms, a marked myeloid stimulation likewise occurred. Of the total leukocytes present, 22.6 per cent were myelocytes, 7.0 per cent were metamyelocytes, and 46.6 per cent were mature neutrophilic granulocytes. Thus, of the total number of circulating leukocytes, 76.2 per cent were neutrophilic granulocytes. The parenteral administration of the factor was more effective than providing the factor in the diet.

PERNICIOUS ANEMIA AND SUSCEPTIBILITY TO GASTRIC NEOPLASMS

HENRY S. KAPLAN, M.D., NEW HAVEN, CONN., AND LEO G. RIGLER, M.D.,
MINNEAPOLIS, MINN.

WITHIN the past fifteen years, increasing attention has been drawn to the coexistence of pernicious anemia and epithelial tumors of the stomach. That this association is more than accidental has been demonstrated by a number of large-scale statistical studies of both post-mortem and living cases. Nevertheless, clinical recognition of this fact has been limited and efforts at utilization of pernicious anemia as an "indicator" for the detection of gastric carcinoma in its early stages have been all too few. For this reason, it was thought worthwhile to review the evidence on this subject anew and to discuss its significance in gastric cancer detection programs.

STATISTICAL CONSIDERATIONS

The numerous individual case reports of coexisting addisonian anemia and gastric cancer have been collected by Cotti,¹⁰ Kaplan and Rigler,²⁸ and others. These have little or no statistical value and will be omitted from this discussion. Similarly, reports of multiple cases of this type have been published by Jenner,²⁰ Strandell,³¹ Cotti,¹⁰ Murphy and Howard,⁴¹ and others. In most of these the anemia had been present for years before the appearance of the gastric tumor, the longest interval being seventeen years in the case cited by Miller.³⁸ This observation was confirmed by Doehring and Eusterman,¹² who found that the average duration of pernicious anemia prior to the onset of symptoms attributable to the gastric cancer was 8.7 years in their series.

Comparison of the reports from the Mayo Clinic over a period of twenty-five years reveals a distinct increase in the incidence of gastric cancer in patients with pernicious anemia. In the first publication by Giffin and Bowler,¹⁷ only one gastric carcinoma and four other malignant tumors were noted in a series of 628 cases. In the period from 1925 to 1930, Conner and Birkeland⁹ found twenty cases of cancer of the stomach among 658 patients with pernicious anemia. Washburn and Rozendaal⁶² collected eleven more such cases in the next three-year period. Finally, Doehring and Eusterman¹² reported seventeen additional cases in a series of 1,014 patients with pernicious anemia studied from 1935 to 1939. The greatly increased life expectancy of individuals with addisonian anemia since the introduction of liver therapy is generally offered as an explanation for this apparent increase in gastric cancer morbidity among them.

Not only cancer but adenomatous polyps of the stomach have frequently been reported in association with pernicious anemia.^{12, 19, 62} Velde⁶⁰ found six such cases (14 per cent) in a series of forty-two patients with pernicious anemia,

From the Department of Radiology, Yale University School of Medicine, and the Department of Radiology and Physical Therapy, University of Minnesota Medical School.

as contrasted with an incidence of 0.71 per cent in a control series of 1,271 patients with other diseases. Such observations assume added significance when the apparently precancerous nature of gastric polyps is considered. In 1930, Miller and associates³⁹ reported eight personal cases and twenty-four others from the literature in which adenomatous gastric polyps had developed into frank carcinomas. Stewart⁵³ found carcinoma associated with thirteen of forty-seven gastric polyps, and several other observations of similar character have since appeared.^{32, 35, 44} Accordingly, the demonstration of a gastric polyp in association with pernicious anemia may be considered to approach in significance the demonstration of carcinoma *per se*.

These case reports, even in large series, are merely suggestive of a relationship between the two diseases. A statistical approach is essential to determine whether the frequency with which they are associated is greater than can reasonably be expected on the basis of chance alone. Several studies of this type have appeared, all of which have revealed a frequency of coexistence significantly greater than would have been predicted by probability.

Rambach⁴³ encountered 641 cases of gastric carcinoma and fifty of pernicious anemia in a series of 11,849 post-mortem examinations. In eleven cases the two diseases were present together, an incidence roughly five times greater than that due merely to chance. Jenner²⁶ noted five gastric carcinomas, four benign gastric tumors, and only one extragastric malignant neoplasm in a series of seventy-six autopsied cases of pernicious anemia. Brown⁵ studied 151 cases of pernicious anemia in a total of 18,200 post-mortem examinations; twelve of these (8 per cent) had gastric polyps and one had a carcinoma of the stomach. The incidence of gastric polyps in the other autopsies is given as 0.003 per cent, which must be an error. However, even when the generally reported autopsy incidence of 0.5 per cent is used for comparison, the number of polyps in the pernicious anemia series is still significantly high.

In addition to the cases found at necropsy, some statistical studies on the morbidity of coexistent pernicious anemia and tumors of the stomach have appeared. Jenner²⁶ discovered eight cases of gastric cancer in 181 patients with pernicious anemia. He computed the expected morbidity of gastric cancer per decade among the living population of Amsterdam and found that the actual frequency in his pernicious anemia series was twelve times that in the "normal" population of comparable age. Van der Sande⁵⁹ similarly calculated morbidity statistics and likewise concluded that the two diseases were associated more often than chance alone would decree. Cotti¹⁰ compiled all of the published case reports in which pernicious anemia had been associated with a malignant tumor and found that the stomach was the primary site in ninety-three of 107 cases, or 86 per cent of the entire series. Since cancer of the stomach represents only about 20 to 40 per cent of all cancers in the general living population, the marked predilection for this organ in patients with pernicious anemia is another link in the chain of corroboratory evidence.

In an attempt to eliminate certain possible sources of error in previous publications on the subject, Kaplan and Rigler²⁵ studied all cases of pernicious anemia, carcinoma of the stomach, and carcinoma of the colon, cecum, and rectum

recorded in a series of 43,021 consecutive autopsies performed by the Department of Pathology of the University of Minnesota. When corrections were applied for errors in the recorded diagnosis of pernicious anemia, an estimated total of 293 cases of this disease were available for study. Of these, thirty-six also had carcinoma of the stomach, seven had gastric polyps, and four had carcinoma of the colon, rectum, or cecum. Statistical analysis revealed that only twelve cases of carcinoma of the stomach would have been expected. The probability that the observed number was due to chance alone was less than one in one billion. It is apparent, therefore, from all of the foregoing evidence, that some etiologic relationship must exist between pernicious anemia and gastric epithelial tumors.

THEORETIC CONSIDERATIONS

The precise nature of this relationship, however, is still far from clear. On a purely hypothetic basis at least three possibilities can be enumerated: (1) Pernicious anemia directly produces a precancerous state in the stomach; (2) gastric cancer causes pernicious anemia; and (3) the two diseases are linked through a precursor or manifestation common to both.

It seems very unlikely that pernicious anemia is a direct cause of gastric tumors, although conclusive proof to this effect is lacking. That the disease is often in remission at the time when the cancer appears is a common observation, and Dyke and Harvey¹³ observed several patients in whom adequate anti-pernicious anemia therapy for a number of years did not prevent the development of gastric carcinoma. The incidence of gastric cancer does not appear to be elevated in patients with other types of anemia, which suggests that anemia per se is not an important etiologic factor.

If cancer of the stomach were caused by exogenous agents in the diet, acting while in direct contact with the gastric mucosa, then the observation by Jacobson and Palmer²⁵ of prolonged gastric emptying time in patients with pernicious anemia in relapse might throw some light on the association of the two diseases. Although Roffo⁴⁶ has reported the induction of gastric tumors in rats fed heated fats or cholesterol, Kirby²⁹ and others have been unable to corroborate these results, and gastric carcinogens in the human diet are still hypothetic.

Cayer and associates⁶ studied vitamin levels in patients with pernicious anemia and found that the levels of nicotinic acid, riboflavin, and thiamin were all significantly reduced. Although vitamins play a selective and important role in the experimental induction of liver cancer, their possible relation to gastric cancer development is entirely unknown.

Likewise, the possibility that gastric cancer causes pernicious anemia can be quickly disposed of by recalling that in many instances where the two have been associated, the latter disease was present for a number of years prior to the appearance of the neoplasm. Because of the frequent occurrence, in patients with gastric cancer, of macrocytic anemias superficially resembling pernicious anemia, some confusion on this point appears to have existed in former years.

In a recent hematologic survey of 127 patients with gastric cancer, Oppenheim and co-workers⁴² found a state of anemia in seventy-eight, or 64 per cent.

The anemia was macrocytic in twenty-five cases, normocytic in thirty-five, and microcytic in eighteen. Leukopenia was absent in all but one, sternal marrow studies did not show failure of maturation and the other characteristic features of pernicious anemia, free hydrochloric acid was often present in the gastric secretions, and a typical reticulocyte response to intramuscular liver extract could not be elicited in some of these cases. Inasmuch as evidence of extensive hepatic insufficiency had previously been found in many patients with carcinoma of the stomach,¹ these authors were inclined to attribute the macrocytic anemias observed in their series to hepatic damage. No instance of true pernicious anemia was encountered in this study, a fact which seems at variance with the evidence previously presented. However, the incidence of pernicious anemia in other large series of gastric cancers, though significantly elevated, has still been only a few per cent. Moreover, in a number of personally observed cases, patients with treated pernicious anemia in remission developed microcytic anemias due to chronic hemorrhage following the appearance of their gastric cancers. In such cases the existence of an underlying pernicious anemia would have been completely masked except for the previous history. It is obvious, therefore, that in the series reported by Oppenheim and associates⁴² the few cases of pernicious anemia that might ordinarily have been expected could well have been absent on a chance basis alone or obscured by the development of some complication such as chronic blood loss.

It is, of course, theoretically possible for a diffusely infiltrating cancer to destroy the entire gastric mucosa responsible for the formation of "intrinsic factor" and thus produce "secondary" pernicious anemia. Until recently, the absence of this complication in subtotally gastrectomized patients²³ was difficult to reconcile with the demonstration by Meulengracht³⁶ that the pyloric portion of the sheep stomach was the site of formation of intrinsic factor. This discrepancy has been resolved by the work of Fox and Castle,¹⁶ who found that the human stomach differs from that of the sheep by the fact that the intrinsic factor is elaborated in the fundic rather than in the pyloric portion. Thus, gastrectomy would have to be *total*, including the entire cardia, in order to produce pernicious anemia as a sequel. In a recent review article, Bethell and co-workers² expressed the opinion that all patients surviving total gastrectomy for any prolonged period of time will develop pernicious anemia. Similarly, extensive cancers of the fundus and cardia of the stomach might conceivably cause secondary pernicious anemia, but such instances must be quite rare.

It is apparent, therefore, that the majority of cases in which the two diseases coexist must be explained in some other way. A number of features common to both conditions immediately come to mind as possible links between them. These factors include achlorhydria and achylia, atrophic gastritis, and heredity. A hypothetic diagram representing the possible relationships has been published by Rigler and associates.⁴⁵

Haring¹⁹ suggested that the functional deficiency of the gastric mucosa which results in achlorhydria and achylia also acts as a stimulus to proliferation and finally to neoplasia, in a manner analogous to the development of goiter and adenomas of the thyroid in iodine deficiency states. However, the frequency of

achlorhydria is far greater than that of gastric carcinoma, indicating that it is certainly not a dominant etiologic factor. Bloomfield and Pollard³ closely followed a group of forty-three apparently healthy individuals with persistent histamine-refractory anacidity for a number of years and observed neither gastric cancer nor pernicious anemia in any member of the group.

Gastritis has been considered an etiologic precursor of pernicious anemia.^{14, 22, 28} However, Magnus and Ungley²⁴ carefully studied the stomachs of patients with pernicious anemia and found no inflammatory changes. Simple atrophy of the mucosa in the gastric fundus and corpus was the only consistent abnormality. It has been reported that on serial gastroscopic examination, the atrophy and "gastritis" seen in patients with pernicious anemia in relapse often disappears after adequate liver therapy.²⁷ It is not likely that an essential etiologic factor in a disease would disappear in this manner. Moreover, Mosehcowitz⁴⁰ has pointed out that achlorhydria and achylia frequently exist for years in the absence of atrophic gastritis, the latter appearing only after the other manifestations of pernicious anemia become apparent. Thus, the weight of evidence would indicate that gastritis is not necessarily a causative factor in pernicious anemia.

The alternative possibility that gastritis is a precancerous lesion has been expounded for years by Konjetzny³¹ and others. The frequent demonstration of gastritis in cancerous stomachs naturally suggests a causal relationship, and Warren and Meissner³¹ have pointed out the histologic similarity between the severe epithelial changes in some cases of gastritis and the morphologic appearance of known precancerous lesions elsewhere. Torgerson²⁸ studied the distribution of gastric cancers in unselected cases and in patients with associated pernicious anemia and found that the proportion of tumors arising in the fundus was distinctly higher in the latter group. Because of the known tendency of mucosal atrophy in pernicious anemia to affect the fundus and corpus more than the pylorus, he felt that this distribution of tumors argued for the precancerous nature of atrophic gastritis. However, such evidence is only circumstantial; the careful studies of Hebbel²⁰ and Guiss and Stewart¹⁸ have failed to demonstrate that gastritis is more common in cancerous stomachs than in those of other individuals of comparable age. Thus, although we cannot refute the possibility that chronic gastritis leads to gastric cancer, present evidence lends little or no support to this view.

The observation of familial tendencies in both pernicious anemia and gastric cancer indicates that common constitutional or hereditary factors may link the etiologies of the two diseases. Conner⁸ first demonstrated the high incidence of achlorhydria in relatives of patients with pernicious anemia. Schwartz⁵⁰ reported that 18 per cent of a series of patients with pernicious anemia also had relatives with the disease. Among the numerous individual case reports in which pernicious anemia appeared in more than one generation of the same family are those of Faber and Gram¹⁵ and MacLachlan and Kline.³³ The evidence for a familial component in the etiology of pernicious anemia has been summarized and discussed at length by Meulengraet³⁷ and by Mosehcowitz.⁴⁰

Pernicious anemia and gastric cancer have been reported separately or together in several members and in more than one generation of many families. The cases of Borovanská-Felklová⁴ and Thiele⁵⁷ are particularly striking examples of this type. Zancan,⁶³ in a genealogic study of seventy-four patients with pernicious anemia, found evidence of nine carcinomas among their blood relatives, of which six arose in the stomach. He traced a parallel series of relatives of patients with gastric cancer and found that their incidence of gastric cancer was actually lower than that of the group related to patients with pernicious anemia. While such observations are not statistically conclusive, present evidence, though inadequate, favors the thesis that the two diseases are linked through common hereditary influences.

Ivy²⁴ recently suggested that a study of blood groups in patients with these coexisting diseases and in their blood relatives might yield further information along these lines. In his opinion, the fact that the gastric mucosa is a known storage site for the blood group-specific agglutinins may even have a direct bearing on the incidence of gastric cancer.

One additional hypothesis remains to be discussed. The increasing number of case reports of coexisting pernicious anemia and gastric cancer since the advent of liver therapy was attributed by Saltzman⁴⁸ to the longer survival period of patients with pernicious anemia, a view that has been generally accepted. However, Teuff⁵⁶ rejected this explanation and speculated that liver extract itself might contain a weak carcinogenic agent which on prolonged administration could lead to cancer in susceptible individuals. This rather startling suggestion finds some experimental support in the work of Kleinenberg and associates,³⁰ Steiner,⁵² and several others who have shown that certain fractions of the livers of both cancerous and noncancerous individuals, when injected into mice or rats, will elicit malignant neoplasms at the site of injection in a small percentage of animals. It has been demonstrated by Strong and co-workers⁵⁵ that animals genetically selected for resistance to the local effects of a carcinogen may exhibit secondary susceptibility to the same agent at a remote site. In the light of such evidence, the possible carcinogenicity of therapeutic liver extracts may well deserve further study.

THE EARLY DETECTION OF GASTRIC CANCER

Recent advances in surgery have made possible the salvage of at least 25 per cent of patients with early, operable cancer of the stomach. Refinements in gastroscopic and roentgenologic technique have greatly improved the accuracy of diagnosis of such lesions. Were it not for the fact that early gastric cancer is generally asymptomatic, a considerable proportion of patients now dying of this condition could be saved. Thus, the chief problem in gastric cancer is becoming, more and more, its detection on a practical scale in asymptomatic individuals.

The most obvious way to attack this problem is to examine routinely, by roentgenologic or gastroscopic methods or both, all patients in the gastric cancer-bearing age. However, morbidity statistics compiled by Collins and associates⁷ indicate that at any one time only three individuals per 1,000 in the

living population over 40 years of age would be likely to have a carcinoma of the stomach. On the basis of these figures, any mass survey in which no selection of patients was employed would entail an enormous expenditure of time, effort, and money with a very small yield of tumors. This prediction has been confirmed by the work of St. John and co-workers.⁴⁷ These investigators, using a rapid fluoroscopic technique, examined over 2,400 asymptomatic individuals past 50 years of age and discovered only two carcinomas and one lymphosarcoma of the stomach. More recently, Dailey and Miller⁴⁸ studied 500 apparently healthy men 45 years of age or over and encountered no malignant tumors of the stomach. Such results emphasize the necessity of *selecting* patients for routine periodic examinations of the stomach on the basis of some pre-existing disease, symptom, or other criterion with which the occurrence of gastric cancer can be shown to be associated more frequently than in the general population.

To date, the only known indicator of this type is pernicious anemia. Two years ago, Rigler and associates⁴⁹ presented the results of serial roentgenologic and gastroscopic examinations in a series of patients with this disease. At that time, 211 patients had been examined one or more times; of these, seventeen (8.0 per cent) were found to have carcinoma of the stomach, and fifteen (7.1 per cent) had benign polyps. Since then, forty-eight new cases of pernicious anemia have been examined at the University of Minnesota, yielding one additional gastric cancer and two individuals with benign polyps. The summarized data are given in Table I. Comparison of these results with the morbidity, previously cited, of gastric cancer in unselected cases of comparable age reveals clearly the striking "concentration" of carcinomas of the stomach in patients with pernicious anemia.

TABLE I. CLINICAL RESULTS

TOTAL NUMBER OF PATIENTS WITH PERNICIOUS ANEMIA EXAMINED	CARCINOMA OF STOMACH FOUND	BENIGN POLYPS OF STOMACH FOUND	TOTAL TUMORS OF STOMACH FOUND
259	18 (6.9%)	17 (6.6%)	35 (13.5%)

Although no large-scale program of gastric cancer detection has yet been established at New Haven Hospital, even a casual survey of patients with pernicious anemia followed for a reasonable period of time reveals that several have developed polyps, and carcinomas are known to have appeared in at least two such patients, one of whom is alive and well almost two years after gastrectomy.

Unfortunately, patients with pernicious anemia represent a very small fraction of those susceptible to gastric cancer. Other indicators must be determined by careful clinical studies on large groups of variously categorized patients. A large-scale investigation of this type is now in progress at the University of Minnesota, the preliminary results of which were recently reported by State and Wangensteen.⁵¹ Achlorhydria, chronic gastritis, gall bladder disease, and anemia have all been used as criteria for the selection of

patients in this study, and relatives of patients with gastric cancer are also being serially examined. It is to be hoped that the final data will permit the nationwide establishment of selective gastric detection programs from which a high yield of early tumors may confidently be expected.

SUMMARY AND CONCLUSIONS

1. Statistical analyses reveal that pernicious anemia and carcinoma of the stomach develop in the same individuals more often than would be expected on the basis of chance alone and must, therefore, be etiologically related.

2. The evidence pertaining to the nature of this relationship is still inconclusive but suggests that the two diseases are probably linked indirectly through the medium of some common factor. Among the possible factors to be considered are hereditary or constitutional tendencies, achlorhydria, gastritis, and liver therapy.

3. In contrast to the paucity of gastric tumors discovered in nonselective mass surveys, serial gastric examination of individuals with pernicious anemia has yielded a very high incidence of benign and malignant epithelial tumors of the stomach.

4. It is suggested that a search for other conditions etiologically related to or associated with gastric cancer is a necessary prerequisite to the establishment of practical, selective mass surveys for the early detection of neoplasms of the stomach.

THE RADIOSENSITIVITY OF ERYTHROBLASTS

MARGARET A. BLOOM, M.S., AND WILLIAM BLOOM, M.D.
CHICAGO, ILL.

ALTHOUGH it is generally agreed that the bone marrow may be made extremely aplastic as a result of irradiation, opinion has differed as to the relative sensitivities of the various cell lineages. The attention of most investigators seems to have been directed to a study of the effect of irradiation on the granulocyte precursors. Heineke (1903, 1905), in his classical paper on the effects of x-rays on bone marrow, saw clearly the destruction of myelopoiesis but hardly considered the question of the effect of irradiation on erythropoiesis. However, the great numbers of degenerating lymphocytes which he described were probably degenerating erythroblasts. A number of investigators, including Milchner and Mosse (1904), Aubertin and Beaujard (1905), and Jolly (1924), reported that erythroblasts are more resistant than the other myeloid cells. Krause and Ziegler (1906), Lacassagne and Lavedan (1924), Halberstaedter and Simons (1933), and den Hoed, Levie, and Straub (1938) found that after heavier or repeated treatment, the erythroblasts also show evidence of injury. The divergent opinions on the relative radiosensitivity of erythroblasts are reviewed by Selling and Osgood in Downey's *Handbook of Hematology* (1938). More recently, in Shields Warren's review (1942), Dunlap concludes: "Similarly, the erythropoietic tissue, according to the majority of observers, shows considerable initial radioresistance, but once it is damaged its ability to recover is limited."

Our own observations on the effect of radiation on the bone marrow of rabbits, rats, mice, and chickens have shown the erythropoietic cells to be among the most sensitive of all hematopoietic cells. The findings which have led us to this conclusion will be given briefly in this report. A more detailed presentation will be found in Chapter VI of our report on the "Histopathology of Irradiation From External and Internal Sources" in the Plutonium Project Reports.

MATERIALS AND METHODS

The effects on bone marrow of total body irradiation by single doses of x-rays, fast and slow neutrons, and of radiations from internal sources (strontium⁹⁰, barium¹⁴⁰, lanthanum¹⁴⁰, phosphorus³², sodium²⁴, yttrium⁹¹, radium, and plutonium) were studied as part of the program of the Histology Group of the Health Division, Metallurgical Laboratory, University of Chicago. For most of the experiments the species used were mice and rats. In addition, a large number of chickens and rabbits were exposed to x-rays and two series of rabbits to fast neutrons. In general, the dosages used were the LD 50/30 days.* Lower doses also were used, these being decreased until morphologic changes were no

From the Metallurgical Laboratory, University of Chicago, and the Argonne National Laboratory.

This work was carried out under contract between the University of Chicago and the Manhattan District, Corps of Engineers, War Department.

*The dose which kills 50 per cent of the animals within thirty days.

longer found. For each experiment a group of animals of the same strain and comparable weight and age was irradiated and sacrificed at predetermined intervals. Untreated controls were sacrificed at the same intervals.

X-rays of 200 kvp were filtered with 0.5 mm. of copper and 1.0 mm. of aluminum (Hagen and Zirkle, 1946). The animals were held in plastic boxes and were rotated at least once during the course of the exposure. The distance varied somewhat with the size and number of animals treated at one time, but it was between 70 and 90 cm., giving from 15 to 11 r per minute.

Fast neutrons were primarily from the Clinton pile (Zirkle and Raper, 1946). Some rabbits were exposed to fast neutrons from the University of Chicago cyclotron (Hagen and Zirkle, 1946).

Slow neutrons were given to mice in boron-lined lead boxes inserted in the Clinton pile tunnels (Zirkle and Raper, 1946).

Internally administered β and γ emitters included sodium²⁴, barium¹⁴⁰, lanthanum¹⁴⁰, strontium⁸⁹, and phosphorus³² injected intraperitoneally, and yttrium⁹¹ injected intravenously.

Among α emitters, plutonium nitrate or citrate (Sayder and Finkle, 1946) was administered intravenously to mice and rats, or intramuscularly to mice. Radium from which the radon had been blown off twenty-four hours earlier (Norris, Tompkins, and Finkle, 1946) was given intraperitoneally to mice and rats.

Femurs of rats and mice were opened at autopsy by shaving nearly to the midline with a sharp knife, and the entire bone then was fixed in Zenker-formol. To secure the bone marrow of rabbits and chickens, the bone was chipped from the shaft of the femur and a pencil of marrow was removed for fixation. The tissue was then embedded in nitrocellulose, sectioned, and stained with hematoxylin-eosin-azure II.

RESULTS

Irradiation From External Sources.—After x-irradiation the degenerative changes in the bone marrow were of similar type in the rabbit, mouse, rat, and chicken. With the LD 50/30 days, mitotic activity ceased and hematopoietic cells were destroyed, in every case erythroblasts before myelocytes. In the rabbit, as early as one-half hour after treatment, the erythroblasts were already reduced in number, and the remaining ones were predominantly late forms (normoblasts). Degeneration of hematopoietic cells continued at subsequent intervals, and by twenty-four hours erythroblasts had dropped to a minimum. Myelocytes, disappearing less rapidly and their destruction sometimes preceded by bizarre forms, reached a low point at 9 days. Megakaryocytes apparently suffered only occasional damage the first day, but by 2 days few were left. The debris was ingested by phagocytes, and the depleted marrow was replaced first by a gelatinous material and then by fat cells. Reticular cells were never found damaged. As the cells began to regenerate, there was an increase in mitotic figures, a preponderance of young forms of hematopoietic cells, and a diminution of fat cells.

In rabbits exposed to 400 r of x-rays, erythropoiesis in the bone marrow was again affected earlier than granulocytopenia, the results differing from those following the higher dose only in degree of damage and in time of its occurrence. Here fewer of the total number of cells were completely destroyed. Lobing of the maturing erythroblasts occurred abnormally early and was excessive. Megamyelocytes appeared, rivaling the megakaryocytes in size. These matured into giant granulocytes with 8 to 12 lobes to the nucleus and eventually degenerated in the marrow.

In rabbits exposed to 100 r of x-rays, the effects on the bone marrow were much less intense and less persistent than those which followed the 400 r dose. While mitosis stopped almost completely, it had been resumed by 3 hours after treatment and continued through the 14-hour interval at a level slightly above that seen in controls. At 8 hours a number of abnormal mitoses were observed; there were also a few dead cells, mostly erythroblasts, occasional nuclei with clumped chromatin, and rare megamyelocytes. From 14 hours through 21 days these marrows were no different from the controls.

In mice exposed to 350 r of x-rays, well below the LD 50/30 days for this species, the general progression of damage and repair of hematopoietic cells was like that observed in the rabbits, again with depletion first most marked in the erythrocytic series, but with myelocytes involved later. Recovery was indicated at 5 days, and was further advanced at 9 and 14 days.

In rats exposed to 600 r of x-rays, the LD 50/30 days, hematopoiesis, normally similar to that in mice, was almost completely eliminated by 2 days after treatment, the depleted areas filling with gelatinous or fatty marrow, but was nearly restored at the 31-day interval. At 3 hours erythroblasts were markedly reduced in number and there was considerable cellular debris. By 14 hours erythroblasts were almost completely gone. Myelopoiesis disappeared rather more slowly but by 2 days was practically absent. Regeneration, observed at 9 days with the return of erythropoiesis, was increased at 14 days with a preponderance of young forms. At subsequent intervals this function appeared normal, except for a possibly significant retrogression in the 21-day specimens. Myelopoiesis continued to be depressed until about 31 days.

The chicken bone marrow was affected by all doses from 25 to 1,000 r, the damage being roughly proportional to the size of the dose. Only 800 and 1,000 r resulted in the production of gelatinous marrow, and after these doses no permanent regeneration was observed in the 9- and 4-day duration of these experiments.

In 3-week chicks exposed to 800 r, erythropoiesis was completely removed at 1 hour and granulopoiesis was gone at 14 hours. Transient waves of regeneration were seen in the erythropoietic series at 2 to 14 hours and at 2 to 5 days; in the granulocytic series the recovery attempts were observed at 5 hours and again at 1 to 4 days. These recovery efforts were futile, however, and the marrow at 9 days was entirely aplastic. In the 11-week chickens two similar waves of regeneration were seen in the granulocytic series.

The presence of lymphatic nodules in the chicken marrow made it possible, in the same organ, to compare damage to lymphocytes with the effects on erythroblasts and myelocytes. Also, since erythropoiesis is intravascular and myelopoiesis is extravascular in the bone marrow of this species, it is less difficult to differentiate between very early forms of these two cell lineages than in the mammalian marrow where the two processes are intermingled.

Certain immature cells in the chick marrow proved more resistant to x-ray treatment than others. Most of the large lymphocytes of the lymphatic nodules

and the few stem cells among the myelocytes were intact at intervals when the small lymphocytes were extensively damaged and the basophil erythroblasts had been totally destroyed.

These differences in susceptibility among cell types were observed not only in the 3-week chicks given 800 r, but also in the 11-week chicks given 800 r and in the 3-week chicks given 400 r. In the older birds the small lymphocytes in the lymphatic nodules were dead at 1 and 3 hours, but the large lymphocytes were intact. All the basophil erythroblasts were dead in the sinuses, while extravasicularly many normal myelocytes remained. Following 400 r in the younger chicks, the destruction was less severe but the differences in sensitivity were even clearer than after the higher dose. In the lymphatic tissue of the marrow, only some of the small lymphocytes were dead at $\frac{1}{2}$ hour, and while the few hemocytoblasts present with the myelocytes appeared to be unaffected, all basophil erythroblasts inside the sinuses had been destroyed.

The pattern of degeneration and subsequent recovery of the bone marrow of rabbits exposed to fast neutrons was strikingly similar to that observed after x-irradiation. Three hours after exposure to 117 n* the degeneration of erythroblasts was at its peak; 5 hours later the destruction was still prominent and quantities of debris were being phagocytosed. The damage to myelocytes was not conspicuous until 17 hours and reached a maximum at 26 hours, occurring later than the damage to erythroblasts, as in the x-irradiated animals. Progressive cellular depletion, the development of gelatinous marrow, and the eventual restoration of hematopoiesis followed.

In the bone marrow of mice exposed to fast neutrons, hematopoietic cells were destroyed to a degree related to the size of the dose. Especially after the lowest dose used, 65 n, it was quite clear that erythroblasts were the first of the hematopoietic cells destroyed.

Again, after exposure of mice to slow neutrons (400 arbitrary units), the same sequence of cellular destruction occurred. At the early intervals the bone marrow contained an increasing amount of debris and damaged hematopoietic cells, especially erythroblasts. By 12 hours myelocytes were fewer in number and groups of those present were pyknotic. The depletion increased up to 4 days, with gelatinous marrow as well as greatly widened sinuses replacing the cellular marrow. At the height of depletion the marrow was aplastic, except for spindle cells, plasma cells, some granulocytes, and, in the shaft, a few groups of normoblasts. By 7 days regeneration was well advanced. The sinuses were now only slightly dilated, and granulocytes were markedly increased throughout the marrow, especially in the shaft. Relatively few erythroblasts were present. Megakaryocytes were rare, except for an aggregation of them in one area just below the cartilage plate of one specimen. By 11 days there had been a great increase in hematopoiesis in the epiphysis and metaphysis, as well as in the shaft, with much more of it erythropoietic than before. At 2 weeks regeneration appeared to be complete.

*The letter n signifies a purely arbitrary unit for measuring fast neutrons: 1 n is the amount of neutron radiation which produces a reading of 1 r on a Vioetreen condenser-type r-meter equipped with a 100 r chamber. This meter is commonly used for measuring X and γ rays in r units.

Irradiation From Internal Sources.—When administered internally, certain radioactive isotopes, including some which are almost pure β emitters and others which emit primarily α rays, affect bone marrow in much the same way, qualitatively, as does irradiation from external sources, especially x-rays and neutrons. Hematopoietic cells were destroyed, sinuses became dilated, and the depleted marrow became gelatinous. In contrast to the picture of sudden destruction and subsequent depletion of cells after x-irradiation, the depletion resulting from internal treatment occurred more gradually and was accompanied by very little cellular debris, as there was ample time for its removal by phagocytosis before it accumulated in large amounts. Also the effects on the marrow persisted, their duration depending on the rate of decay of the agent. The order of destruction of hematopoietic cells was the same here as after external irradiation, erythroblasts before myelocytes and myelocytes before megakaryocytes. Free macrophages, reticular cells, and fat cells were radioresistant. These differences between the several cell strains in sensitivity to irradiation were obvious in mice treated with strontium⁸⁹, barium¹⁴⁰-lanthanum¹⁴⁰, phosphorus³², sodium²⁴, plutonium, and radium, and in rats after strontium⁸⁹ and yttrium⁹¹. The location and type of "particle" emitted by the isotope modified the extent but not the quality of the injury. Thus, the short-ranged α particles produced a relatively narrow rim of aplastic marrow around each trabecula in which they lodged. The much longer-ranged β particles produced much broader zones of damage; indeed, the marrow of the long bones of mice became completely aplastic after the deposition of fair amounts of the β emitting isotopes in bone.

CONCLUSIONS

In the bone marrow of mammals exposed to total body irradiation with x-rays and fast and slow neutrons, hematopoiesis is severely depressed, the degree of injury varying with the dose. The changes in the marrow cells after the injection of the radioactive isotopes, especially those that deposit in bone, are much the same as after the radiations coming from external sources. In all cases the erythropoietic cells are more susceptible to damage than the myelocytopoietic ones, and these in turn than the megakaryocytes.

Similar findings were demonstrated in chickens exposed to x-rays. In these animals the intravascular position of erythropoiesis makes the recognition of these cells easy even in hematoxylin and eosin preparations. The erythroblasts are at least as radiosensitive as the smaller lymphocytes of the nodules which are common in chicken marrow. The large lymphocytes are somewhat more resistant than the small ones.

Fat cells, free macrophages, and reticular cells (including those lining the sinuses) seem to be completely radioresistant to the dosage of irradiation we used.

These findings are in general agreement with the observations made by our group in comparing the relative radiosensitivity of the lymphatic versus myeloid cells of the spleen of rabbits and especially of mice and rats.

It is quite probable that those authors who described large numbers of degenerating lymphocytes in mammalian bone marrow after irradiation had confused these cells with degenerating erythroblasts. It may be that the extreme radiosensitivity of erythroblasts has often been overlooked because of the acute changes of the leucocytes in the peripheral blood, in contrast to the minor changes in the long-lived erythrocytes.

THE STRUCTURE OF THE GIANT CELLS IN THE BLOOD-FORMING ORGANS

CAPTAIN JOHN W. REBUCK,* MEDICAL CORPS, ARMY OF THE UNITED STATES

INTRODUCTION

NORMALLY the blood-forming organs, particularly the bone marrow, contain a few scattered giant cells or exceedingly large cells. The megakaryocytes, osteoclasts, and possibly the multinucleated plasma cells belong to this group and play a role in the physiologic processes of the various blood-forming organs in which they are found. More numerous and extremely variegated in structure are the giant atypical mononuclear cells and the polymorphonuclear and multinucleated giant cells frequently observed concomitant with or partaking in pathologic processes in the blood-forming organs. It is the purpose of this paper to make readily accessible brief morphologic descriptions and accompanying photomicrographic representations of both typical and atypical giant cells, much in the manner of an atlas in miniature.

The material and records available at the Army Institute of Pathology and its associated Lymphatic Tumor Registry are admirably suited to this purpose, comprising as they do numerous examples of all the common pathologic processes and most of the rarer ones. Furthermore, the diagnostic identification of the more controversial processes is usually a composite of the studies and opinions of many different pathologists representing diverse schools of thought and including specialists in the fields of hematology and hematopathology as well as general pathology. For example, only those cases were utilized in studying the giant cells in reticulum cell sarcoma of the lymph nodes in which the diagnosis of reticulum cell sarcoma was essentially agreed upon by all the consultants.

In the preparation of this paper the author has made frequent use of Haythorn's¹ exhaustive review of the literature on the giant cells with especial reference to the foreign body group.

MATERIALS AND METHODS

The material available comprised clinical records, autopsy or surgical protocols, and formalin-fixed tissues, with the addition, in many cases, of dry-fixed smears or impressions of the hematopoietic organs. All cases had been studied in hospitals. Paraffin sections were prepared from all formalin-fixed tissues and were stained with hematoxylin and eosin. In instances of disturbances in the metabolism of lipids, various fat stains were used. To meet the requirements of individual cases, Wilder's method for reticulum, MacCallum's stain for bacteria, and Kinyoun's stain for acid-fast bacilli were employed. The dry-fixed smears and impressions were stained by the Romanowsky methods, Wright's stain or, preferably, Wright-Giemsa or May-Grünwald-Giemsa, as employed by Slider and Downey² and Kolouch.³ Impressions are obtained by touching a fresh cut surface of tissue to a clean slide, so lightly that but a single

From the Army Institute of Pathology, Washington, D. C.

*Present address: Department Laboratories, The Henry Ford Hospital, Detroit, Mich.

layer of cells adheres to the glass. The slide is immediately air-dried without the application of heat and is then ready for staining. The imprint method is preferable to smears because the cells are less likely to be distorted and ruptured in the process.

The photomicrographs were all taken at the same magnification ($\times 2000$) so that ready comparison of the size of the various structures could be made by the reader. Account must be taken, however, of the shrinkage due to fixation when comparing the size of cells in sections and imprints. The higher power was employed because a number of the cells herein discussed have been depicted at extremely low magnification or not at all in the literature, although the majority have been excellently portrayed.

OBSERVATIONS

A. THE MEGAKARYOCYTES.—In 1890 Howell⁴ differentiated a new type of giant cell in the bone marrow from the osteoclast type originally described by Kölliker.⁵ To this separate class of cells Howell gave the name "megakaryocyte." In 1906 Wright⁶ traced the origin of the blood platelets from Howell's megakaryocytes. The morphologic descriptions which follow will serve as a basis for comparison of these cells with the various more or less characteristic giant cells to be found in Hodgkin's disease and reticulum cell sarcoma, structures with which megakaryocytes are closely identified by some observers. For further details of megakaryocytic morphology the reader is referred to the recent reviews by Rosenthal¹⁶ and by Dameshek and Miller.⁷

1. *Megakaryoblast.*—

Morphologic Characteristics in Dry-Fixed Smears or Imprints: This cell is slightly larger than the myeloblast (hemocytoblast) which it rather closely resembles. The megakaryoblast has a round or slightly irregular nucleus and a thin nuclear membrane. The nuclear pattern is produced by small chromatin particles arranged in a fine sievelike or a dark regularly stippled design, somewhat coarser than that of the myeloblast. The parachromatin spaces (karyoplasm) are characteristically pink and sharply demarcated from the chromatin particles, but the nuclear pattern is generally slightly less leptochromatic than that of the myeloblast. One or more nucleoli may be present. The nuclear-cytoplasmic ratio favors the nucleus. The cytoplasm, which forms a narrow rim about the nucleus, is basophilic and nongranular. I have not included an illustration of this cell, which actually is not a giant cell; however, the papers of Jürgens and Graupner,⁸ Strumia,⁹ Rohr,¹⁰ and Dameshek and Miller⁷ present good colored representations of this cell type.

Morphologic Characteristics in Tissue Sections: The megakaryoblast is slightly larger than the hemocytoblast (Fig. 1). Its cytoplasm shows a lessening in basophilic properties. The nuclear membrane is thicker than that of the hemocytoblast and the chromatin masses are coarser, although a nucleolus occasionally may be made out. This cell can be identified in sections only by the nature of its associates in areas of intense megakaryocytic metaplasia.

Origin: Ordinarily this cell is derived from the myeloblast (hemocytoblast) (Ferrata and Negreiros-Rinaldi¹¹ 1915, Downey and Nordland¹² 1939) and from

the reticulum cell (hemohistioblast) (Custer¹³ 1933, Downey and Nordland¹² 1939, and Dameshek and Miller⁷).

2. Promegakaryocyte.—

Characteristics in Dry-Fixed Smears or Imprints: The size of this cell varies from that of the megakaryoblast to well over 20 microns in diameter (Figs. 2 and 3). The nuclear membrane is thin; the nucleus is larger than that of the megakaryoblast; and the nuclear pattern may retain the fine chromatin-parachromatin features of the latter, although it is usual for masses of clumped chromatin to make their appearance in a few areas at this stage. The clumped chromatin is presented in Fig. 3, whereas the cell in Fig. 4 has largely retained the megakaryoblastic pattern. The nucleus may be round or nuclear lobulation may begin at this stage. In general, the nuclear texture is heavier and nucleoli are usually absent. The cytoplasm is basophilic, scant or abundant, and often presents a fine azurophil granulation about the nucleus. Frequently, as seen in the excellent figures of Downey and Nordland¹² and Dameshek and Miller,⁷ granular, occasionally nongranular, platelet-like forms are to be found at the cytoplasmic periphery. The larger cells of this group (Figs. 4, 5) are actually intermediate between promegakaryocytes and megakaryocytes.

Characteristics in Tissue Sections: In tissue sections the promegakaryocyte is larger than the megakaryoblast; both nucleus and cytoplasm are increased in size, and the nuclear membrane is thicker. The chromatin masses are larger and coarser, and the vesicular appearance of the hemoerythroblast is entirely lost. Lobulation of the nucleus may occur (Fig. 6) or the nucleus may remain round but slightly irregular (Fig. 7). If an appropriate fixative, formal-corroasive (Downey¹⁴), and stain, Giemsa, Wright's or Dominici's (Slider and Downey²), are employed a small azurophilic or acidophilic granular area appears in the cytoplasm eccentrically near the nucleus and gradually spreads until the entire cytoplasm becomes granular. Unfortunately, ordinary tissue methods fail to bring out cytoplasmic detail in cells of this series.

Origin: Ordinarily the promegakaryocyte evolves from the megakaryoblast although in intense reticular stimulation it can also be derived from the reticulum cell.

3. Megakaryocyte.—

Characteristics in Dry-Fixed Preparations: The megakaryocyte is usually a very large cell, well over 40 microns in diameter. The nuclear membrane is thick, and the nucleus is large, polymorphous (Fig. 8), and extremely complicated in form. The original chromatin-parachromatin distinction may be all but obscured by the coarsening of the chromatin masses, although at times distinct areas of parachromatin can be observed (Fig. 5). The cytoplasm is abundant, basophilic, and contains numerous azurophil granules. Gradually the azurophil granules form into groups surrounded by clearer areas of cytoplasm. Pseudopodial processes at the periphery of the cell are frequently found to contain these platelet-like formations. For further cytologic details and colored figures of these cells the reader is referred to the works of Rohr¹⁰ and Dameshek and Miller.⁷

FIG. 7.—Promegakaryocyte, section of spleen in myeloid metaplasia. Hematoxylin and eosin stain; X2000. AIP Neg. 97014

Characteristics in Tissue Sections: In sections the megakaryocyte may have a diameter as great as 40 microns. The cell outline may be roughly spherical or irregular. The nucleus is large and polymorphous (Fig. 9), the nuclear membrane thick. The chromatin network is composed of coarse dense chromatin strands. Nucleoli are present but usually indistinct. The cytoplasm is abundant and slightly acidophilic. With appropriate fixation and staining, diffuse or grouped azurophil granules are found throughout the cytoplasm. The periphery of the cell is frequently provided with irregular, fingerlike processes of various shapes. In the bone marrow these pseudopodia may be found projecting into the sinuses (Downey,¹⁴ his Fig. 17). Platelets are formed by the fragmentation of pseudopodial cytoplasm, the azurophil granules serving as the chromomere and the fragments of cytoplasm as the hyalomere of the blood platelet.

Origin: Usually the megakaryocyte is derived from the promegakaryocyte, rarely from the polykaryocyte (Di Guglielmo¹⁵ and Rosenthal¹⁶).

Function: These cells serve to form the blood platelets (Wright,⁶ Bunting,¹⁷ and Downey¹⁴).

4. *Dividing Forms of Megakaryocytes.*—The cells of the megakaryocytic series reach maturity by means of multipolar mitoses (Rohr¹⁰ and Maximow and Bloom¹⁸), in which the cytoplasm undergoes no constriction and the daughter nuclei fuse at once into an increasingly pachychromatic, polymorphous nucleus. The fully mature megakaryocyte probably does not undergo further cell division.

5. *Polykaryocyte.*—Di Guglielmo¹⁵ introduced the concept of the fusion of several histioid elements into a syncytium with multiple nuclei and but a single cell body, which in turn could serve as a source of megakaryocytes. Rosenthal¹⁶ (his Figs. 11 to 13) and Dameshek and Miller⁷ (their Fig. 5) depict such cells. The latter authors believe that these cells are probably identical with osteoclasts. Depicted in our Fig. 10 is a multinucleated megakaryocyte which possesses three discrete nuclear masses yet retains the cytoplasmic and nuclear detail of an ordinary megakaryocyte (compare this cell with Figs. 5 and 8). The concept of a polykaryocytic origin of the megakaryocyte has not received general acceptance. Fig. 10 also should be compared with Fig. 47, an osteoclast obtained from a dry-fixed preparation of the bone marrow. The osteoclast, in contrast to the multinucleated megakaryocyte, presents a marked reticulum cell or histiocytic type of nucleus and deeply basophilic cytoplasm lacking azurophil granules.

6. *Degenerated Megakaryocytic Forms Encountered in the Normal Bone Marrow.*—Upon completion of its platelet-forming function, the cytoplasm of the megakaryocyte, which now has become greatly depleted, disintegrates (Fig. 11). The polymorphous nucleus becomes dark-staining, shrunken, pyknotic, and stripped of almost all of its cytoplasm (Fig. 12). Degenerated megakaryocytic forms are readily confused with the degenerated forms of Reed-Sternberg cells found in Hodgkin's disease (Figs. 26 and 27); therefore, it is imperative that the differential study of these cell types be made before degeneration has progressed to any extent.

7. Pathologic Megakaryocytic Forms.—

a. In idiopathic (essential) thrombocytopenic purpura the megakaryocytes have been described in detail in the works of Frank,¹⁰ Linarzi and Schleicher,²⁰ and Dameshek and Miller.⁷ In brief, the number of these cells in the bone marrow is normal or increased; many of the adult megakaryocytes present absence of azurophil granulation or decrease in pseudopodial and platelet formation (Fig. 13). The promegakaryocytes show an abortive pseudopodial formation which results in the production of giant, atypical, nongranular platelets. There may be a decrease in the number of megakaryoblasts and an increase in degenerated forms. The cytoplasm of the latter may show vacuolization and hyalinization, and the nuclei hyperlobulation, in addition to the features of degenerated forms already described.

b. In hemorrhagic or hemolytic anemias megakaryocytes are increased but platelet formation is abundant.

c. In hemophilia, polycythemia vera, secondary polycythemia, Gaucher's disease, Felty's syndrome, and aplastic anemia, to mention but a few conditions, quantitative but no qualitative changes in megakaryocytes have been described.

d. In myeloid megakaryocytic hepatosplenomegaly cells in all stages of megakaryocytic development are found in the peripheral blood along with bizarre atypical hypergranular or nongranular platelets. Even the megakaryoblasts and promegakaryocytes present atypical abortive pseudopodial platelet formation, spleen, liver, and lymph nodes may show myeloid metaplasia of a megakaryocytic type, but the marrow is not leukemic and may even possess fewer than the normal number of megakaryocytes (Downey¹²). Paseyro²¹ (his Figs. 119 and 122) depicts megakaryocytes in dry-fixed preparations from the spleens of patients with this disease.

e. In chronic myelogenous leukemia any of the conditions existing in myeloid megakaryocytic hepatosplenomegaly may be found, with the addition of similar changes in the megakaryocytic series in the bone marrow and other areas of leukemic "infiltration."

f. In pernicious anemia, Rohr¹⁰ (his Fig. 47) and Paseyro²¹ (his Fig. 45) depict marked hypersegmentation of the megakaryocytic nucleus comparable to the hypersegmentation of the neutrophilic leukocytes in the bone marrow in this disease. Jones²² (his Figs. 10 and 11 and Plate II) found megakaryocytes

PLATE III
(For legend, see opposite page)

with "extremely basophilic cytoplasm and mottled areas of hyaloplasm without evidence of platelet formation" in the bone marrow of patients with pernicious anemia in relapse. Paceyro²¹ (his Figs. 45 and 46) has noted an intense megakaryocytic reaction in one of his patients with pernicious anemia. It should be noted that in this disease another type of multinucleated giant cell occasionally is found in the bone marrow (our Fig. 14); it is made up of reticular promegakaryoblasts with multiple discrete nuclei in a single cytoplasmic mass, which stains with the same intense basophilia as does the cytoplasm of individual promegakaryoblasts. Although the cell illustrated is binucleate, others containing as many as nine nuclei were observed in the same marrow by Dr. R. P. Custer. Rohr¹⁰ (his Fig. 44) illustrates similar reticular-promegakaryoblastic cell masses in pernicious anemia.

g. In secondary toxic thrombocytopenia, Rohr¹⁰ (his Fig. 102) depicts abnormal and incomplete platelet formation in restricted portions of the megakaryocytic cytoplasm.

h. In megakaryocytic leukemia it is possible to observe what may be termed a "malignant" megakaryocytic series. With the leukemic processes centered in cells of the developing megakaryocytic type, one can compare the structure of the resultant leukemic megakaryocytes on the one hand with definitive megakaryocytes and on the other hand with Reed-Sternberg cells of Hodgkin's disease. The leukemic megakaryocytes arise partly from the hemocytoblasts and partly from the reticulum cells (mesenchymal cells) in the bone marrow, lymph nodes, spleen, and other sites of leukemic "infiltration." Three stages in the early development of these cells in the bone marrow are depicted in our Fig. 15. The structure of the young forms in tissue sections is similar to that already described for cells of the definitive megakaryocytic series. The more fully developed forms, such as the cell from a lymph node in Fig. 16, may likewise closely resemble the definitive megakaryocyte (compare with Fig. 9), although many of them present marked variations. Their nuclei may undergo extreme hyperlobulation (Fig. 17) without degenerative changes, the individual nucleus frequently being massive (Figs. 18 and 19). In spite of these changes it should be noted that the nuclear structure remains vesicular, and if the occasional clumps of coarse chromatin are present, they cling to a moderately thick nuclear membrane (Figs. 17 and 19). Two or three of the giant lobes may contain large abnormal

PLATE IV

(For legend, see opposite page.)

basophilic nucleoli; however, they are not a conspicuous feature in the majority of leukemic megakaryocytes, although they are more prominent than in definitive megakaryocytes. Giant bizarre nuclei of the type depicted in Figs. 18 and 19 are not found in definitive megakaryocytic series (compare with Fig. 9). On the other hand, in Reed-Sternberg cells the acidophilic nucleoli are a prominent feature, and cells corresponding to those of the definitive megakaryocytic series (for instance the cell in Fig. 16) are not found in company with the Reed-Sternberg cells in extramedullary malignant lymphogranulomatous areas. The mitoses, as is to be expected in the leukemic megakaryocytic group, are extremely bizarre (Fig. 20). For additional information on cytologic detail it is imperative that such cells be studied by the dry-fixed smear or imprint technique as well as in tissue sections.

B. GIANT CELLS IN HODGKIN'S DISEASE.—The characteristic giant cells in Hodgkin's disease were described first by Sternberg²³ and Reed.²⁴ Reference to their careful and complete descriptions of these cells as they appear in tissue sections should go far in removing the difficulties encountered in the identification of giant cells of this type. For this reason I shall quote their original descriptions.

Sternberg,²³ p. 23 (1898) writes: “. . . ferner grössere, protoplasmareiche Zellen mit grossen, dunkelgefärbten Kernen, die nicht so selten mehrfach zu zweien und dreien oder auch gelappt erscheinen. Vereinzelt solche Zellen besitzen eine grössere Anzahl (bis zu fünf und sechs) Kernen. An manchen sind die Kerne auffallend gross, rund und enthalten sich mit Eosin tingierende Kernkörperchen, oder, was seltener der Fall ist, die Kerne sind blass gefärbt und enthalten einen oder zwei sich mit Eosin färbende Nueleolen. In der Mehrzahl sind sie überchromatinreich. Diese Zellen liegen zumeist frei zwischen den Zügen lockeren Bindegewebes, auch denselben an und manchmal so innig und sind auch mit plumpen Ausläufern versehen, dass sie mit dem Stroma in Zusammenhang zu sein scheinen.”

His Figs. 1 to 4 illustrate the cells he describes.

In 1902 Reed²⁴ describes these cells in the following manner:

“The nucleus is always large in proportion to the size of the cell. It may be single or multiple. If single, it is usually round. Bean-shaped and irregularly indented nuclei are common. If multiple, the nuclei may be arranged peripherally in the cell or heaped in the center. Eight or ten nuclei have been seen in a single cell. The chromatin network is prominent in these nuclei, and one or more large nucleoli are always present. The nucleoli are usually oval but they may be of any shape. The nucleoli always take a contrasting stain in the double stains; they have an affinity for acid dyes. No definite mitotic figures were ever seen in these cells. Direct division was frequently observed. The protoplasm is usually homogeneous and stains well. It may appear granular, show vacuolization, or contain fat or pigment granules. Cells having bizarre and irregular nuclei are found in the oldest growths. These giant cells, so far as our observation reaches, are peculiar to this growth and are of great assistance in diagnosis.”

Her Figs. 2 to 5 illustrate these cell types.

Shown in our Fig. 21 is the enlarged reticulum cell in a case of Hodgkin's disease and in Fig. 22 a similar cell with two large acidophilic nucleoli, thin nuclear membrane, relatively few particles of chromatin, and scant faintly acidophilic cytoplasm. A very similar but binucleate cell of this type is found in

PLATE V

- Fig 29—Atypical enlarged reticulum cell. Imprint of lymph node in Hodgkin's disease. Wright-Giemsa stain, X2000. AIP Neg. 98049.
- Fig 30—Atypical binucleated enlarged reticulum cell. Imprint of lymph node in Hodgkin's disease. Wright-Giemsa stain, X2000. AIP Neg 97903.

Fig. 23. These cells should be compared with Figs. 1 and 7, developing megakaryocytes in tissue sections, which lack the large acidophilic nucleoli and scant chromatin pattern of Reed-Sternberg cells. The simpler form of giant lobulated Reed-Sternberg cell is depicted in Fig. 24. The large round or rod-shaped acidophilic nucleoli, so prominent in these cells, and their relatively moderate chromatin content are in sharp contrast to the nuclear characteristics of intermediate and adult megakaryocytes as seen in Figs. 6, 7, and 9. If further differentiating criteria are required, special fixation and staining (Downey¹⁴) will reveal the azurophil granulation and granular pseudopodial platelet formation on the part of megakaryocyte cytoplasm in tissue sections, two characteristics which are not features of the cytoplasm of Reed-Sternberg cells. Shown in Fig. 25 is one of the larger bizarre cells of the Reed-Sternberg type with excessive nuclear lobulation. Degenerated forms of Reed-Sternberg cells are a constant feature throughout the course of Hodgkin's disease, and they become even more apparent after the application of the various forms of therapy. Such cells undergoing pyknosis or lysis are shown in Figs. 26 and 27. It is not surprising, when we compare these cells with the degenerated forms of megakaryocytes (Figs. 11 and 12) and note the over-all resemblance between the pyknotic polymorphonuclear and multinucleated forms, that these two entire groups are occasionally identified as one, especially since degeneration may occur at any stage of development of the Reed-Sternberg cell. The observation of Reed²³ that mitoses are never found in these cells has been refuted by more recent findings of multipolar mitoses, as illustrated in Fig. 22.

In the dry-fixed impressions of the blood-forming organs, stained by the May-Grünwald-Giemsa technique, the disparity in structure between megakaryocytes and Reed-Sternberg cells is readily apparent. Passeyro²¹ has a comprehensive series of photomicrographs of such preparations (his Figs. 69 to 73 and 75 to 78). In our Fig. 28 is shown the enlarged atypical reticulum cell of this disease. It is comparable to the cell of Fig. 22 as seen in tissue sections. The large size and beginning lobulation of the nucleus become more apparent. The chromatin is arranged in small angular pieces irregularly distributed throughout the nucleus, so as to leave distinct colorless parachromatin spaces. The nucleoli are as yet small, round or irregular, and deeply basophilic. The cytoplasm is abundant and consists of a large amount of flaky, granular, basophilic spongioplasm against a colorless background of hyaloplasm. Very rarely a few scattered azurophil granules are to be found within the cytoplasm, but in only an occasional cell, and the granules are few and never show a tendency to group or clump. Presented in Fig. 29 is a similar giant mononuclear cell with several prominent basophilic nucleoli. Depicted in Fig. 30 is a binucleate cell of the Reed-Sternberg type, lacking prominent nucleoli. Comparison of this illustration with those of the developing megakaryocytes (Figs. 2 and 3), in which the same technique was utilized, reveals a chromatin-parachromatin distinction of the nuclear patterns of the two types but increased clumping of the chromatin particles, absence of numerous or prominent basophilic nucleoli, and beginning azurophil granulation in the cytoplasm about the nucleus of cells of the megakaryocyte series.

PLATE VI

Fig 31—Small Reed-Sternberg cell Imprint of lymph node in Hodgkin's disease Wright-Giemsa stain, X2000 AIP Neg 98050

Fig 32—Reed-Sternberg cell Imprint of lymph node in Hodgkin's disease Wright-Giemsa stain, X2000 AIP Neg 97901

Fig 33—Small Reed-Sternberg cell Imprint of lymph node in Hodgkin's disease Wright-Giemsa stain, X2000 AIP Neg 98048

Fig 34—A part of a large Reed-Sternberg cell Imprint of lymph node in Hodgkin's disease Wright-Giemsa stain, X2000 AIP Neg 97905

In Figs. 31 to 34 is revealed lobulation of the nuclei of the Reed-Stern cells, increasing until they become giant, bizarre, and polymorphous. It is to be noted that the fine reticular chromatin network with its chromatin-parachromatin distinction is retained until and beyond the stage of actual beginning cellular degeneration. The nucleoli, which may reach diameters up to 7 microns (Fig. 34), retain their deep, clear, basophilic staining properties. Instead of containing one or two large nucleoli, each nuclear lobe may be spotted with from six to eight small basophilic nucleoli (Fig. 33). The cytoplasm remains as described in the earlier developmental stages. The fully developed Reed-Sternberg cells should be compared with Figs. 5 and 8, with the more mature megakaryocytes, or with the corresponding figures of adult megakaryocytes from the cases of Dameshek and Miller.⁷ For the more mature megakaryocytes natural pyknosis has gone on to produce a pachychromatic nuclear pattern; large or numerous basophilic nucleoli are absent or masked, and clumping of azurophil granulation, if not pseudopodial platelet formation, is usually apparent in the cytoplasm. Thus, the value of dry-fixed, imprint preparations is enhanced in cases in which Hodgkin's disease of the blood-forming organs is to be differentiated from those primary or secondary affections of the same organs in which megakaryocytic hyperplasia, "infiltration," or metaplasia is a prominent feature.

Function: The enlarged, abnormal reticulum cells of Hodgkin's disease are rarely found to be phagocytic, according to Jaffe.²⁵ But at the Army Institute of Pathology we have observed a case in which the Reed-Sternberg cells contained nuclear remnants and others, lipids. In the latter instance cells simulating Touton giant cells were observed, although the central ring of nuclei presented the nuclear pattern typical of Reed-Sternberg cells rather than of histiocytes.

It should also be emphasized that even the earlier authors mentioned non-specific foreign body giant cells in the primary dyscrasias of the blood-forming organs, in addition to the various specific giant cell forms. Thus, in Hodgkin's disease, Reed²⁴ describes a "second form" of giant cell, similar to the Langhans' giant cell and Mallory²⁶ foreign body giant cells. It is interesting that Langhans²⁷ himself noted the occurrence of cells identical to those which he had observed in tuberculosis, in cases of what he then termed "malignant lymphosarcoma."

C. GIANT CELLS OF RETICULUM CELL SARCOMA.—Tumor giant cells appearing in reticulum cell sarcoma have been described by Oberling,²⁸ Warren and Picena,²⁹ Gall and Mallory,³⁰ Foot,³¹ and many others. The cells are small for giant cells, usually measuring from 15 to 25 microns in diameter; their cytoplasm is customarily scant and faintly acidophilic in tissue sections, whereas the nucleus consists of a giant multilobulated structure occupying almost the entire cell body. The cells of Figs. 35 and 36 are of this type as seen in tissue sections. The nuclear membrane is distinct and the nuclear lobes are characteristically closely affixed to one another. The chromatin content is sparse, giving a pale vesicular appearance to the lobes, which makes even more prominent a large, round or irregular, basophilic nucleolus to be found usually one or two

to a lobe. None of these forms contained the acidophilic nucleoli of the fully developed Reed-Sternberg cells as seen in tissue sections.

D. GIANT CELLS IN LEUKEMIC RETICULO-ENDOTHELIOSIS.—Cases of leukemia in which the leukemic process is centered primarily in the reticulo-endothelial cells as they exert their hematopoietic function, that is, cases characterized by leukemic reticulo-endothelial cells and their differentiation products, have been reported as such by Ewald³² and Downey.³³ Since cases of this nature are usually included in the literature of the monocytic leukemias, the structure of the leukemic reticulum cells has received little attention from other writers. In several cases of leukemic reticulo-endotheliosis in the material available at the Institute, the leukemic reticulum cells or mesenchymal elements of the blood-forming organs were observed in the process of forming giant, bizarre, polymorphonuclear, or multinucleated reticulum cells similar to those found in reticulum cell sarcomas. In dry-fixed impressions of a lymph node in such a case, cells such as those of Figs. 37 to 39 are seen. The nuclei are round, oval or irregular in outline; the chromatin pattern consists of fine to moderate sized chromatin particles, irregularly arranged, but often sharply demarcated from the parachromatin. The nucleoli are basophilic and small but distinct. Three of the nuclei in Fig. 37 are within the main cytoplasmic mass, the other two apparently are within separate cytoplasmic divisions. The nuclear patterns are less leptochromatic than those of normal reticulum cells, and this may be explained in this case by the fact that differentiation was proceeding along lymphocytic and plasmacellular lines. The cytoplasm may be scant or abundant, and the basophilic spongioplasm is arranged in flakes against a colorless or yellowish hyaloplasm.

In tissue sections the nuclei of these reticular giant cells (Figs. 40 and 41) may possess pale or hyperchromatic patterns. The cell of Fig. 40 was the only one found which resembled the Reed-Sternberg cell; however, the basophilia of the large nucleolus in the one lobe, the hyperchromatism of the remaining lobes, and the small size of the nucleus are not characteristics of Reed-Sternberg cells. Compare these cells of leukemic reticulo-endotheliosis with the illustrations of Reed-Sternberg cells (Figs. 22 to 25) and those of the tumor giant cells of reticulum cell sarcoma (Figs. 35 and 36).

E. GIANT CELLS IN METASTATIC TUMORS PRIMARY IN OTHER THAN HEMATOPOIETIC ORGANS.—Metastatic undifferentiated carcinomas frequently simulate the appearance of primary affections of the blood-forming organs, particularly of the lymph nodes. The tumor giant cells of these metastases, then, must likewise

be differentiated from the giant cells in primary affections of the hematopoietic system. A discussion of three of the more common examples of these metastases follows.

1. Transitional Cell Carcinoma.—Transitional cell carcinoma (lympho-epithelioma) metastatic to lymph nodes often simulates reticulum cell sarcoma. In Fig. 42a is shown a cord of epithelial cells cut tangentially and apparently surrounded by lymphoid stroma in such a case. Although many of the epithelial characteristics of these cells have been lost, usually enough remain on which to base a definitive diagnosis. Although individual cellular outlines and intercellular bridges are missing, three distinguishing features are listed by Custer²⁴: they are: overlapping of the nuclei, prominence and large size of many of the nucleoli, and the synektial arrangement of the epithelial growth. The nuclei as seen in sections have a distinct nuclear membrane, scant, fine chromatin granules arranged in a delicate linen network, and a rather prominent, round or oval, acidophilic nucleolus. There is marked variation in individual nuclear size in any particular epithelial cord or nest. Ewing²⁵ points out the alveolar structure and lack of intercellular reticulum after silver staining.

2. Anaplastic Carcinoma.—Anaplastic carcinoma metastatic to lymph nodes may likewise possess morphologic features similar to reticulum cell sarcoma. Figs. 42b and 43 are illustrations of tumor giant cells of an anaplastic carcinoma of the breast metastatic in an axillary lymph node. Usually the functions and hence the special morphologic characteristics of the cytoplasm of the cells in the tissue of primary origin are lost and the cytoplasm is nonspecific, but occasionally special stains will bring out granules or secretory products helpful in the recognition of the true nature of these cells. Otherwise, the tumor giant cells cannot be characterized apart from the extreme diversity of types to be seen in a given lesion. Nuclear lobulations may be few or numerous, nuclear lobes small or large, nuclear outlines extremely bizarre, and nuclei pale and vesicular (Fig. 42b); the more prominent nucleoli are usually acidophilic (Fig. 43). Fortunately, the histopathologic pattern of the metastatic neoplasm, the sheets, cords, or nests of epithelial cells sequestered in the node, is in itself not difficult of recognition. The characteristics of such cells in dry-fixed preparations may be observed in Rohr's²⁶ monograph (his Figs. 120 and 121a) or as illustrated by Paceyro²¹ (his Figs. 30, 33, and 99).

3. Metastatic Malignant Melanoma.—The tumor giant cells of the metastases in tumors of this type present the customary features of the tumor giant cells found in the general group of anaplastic malignancies. Bizarre nuclear outlines, scant or excessive chromatin content, absent or prominent basophilic nucleoli, and moderate or extreme lobulation of nuclei are to be found (our Figs. 44 and 45). Melanin granules may or may not be present within the alveolar type of acidophilic cytoplasm. The dopa reaction should be positive in these cell types. Dry-fixed preparations of similar cells are to be found in Paceyro's²¹ monograph (his Figs. 31, 96, and 97). Strumia⁹ depicts giant, phagocytic, hemohistioblastic cells laden with black pigment derived from broken down malignant melanoma cells (his Fig. 11 and Plate VIII).

F. GIANT CELLS RELATED TO THE SOFT TISSUES OR BONE.—The giant cells in conditions primarily affecting the soft tissues of bones are included in this discussion, not because of any desire to classify the inflammatory and neoplastic lesions of bones among the disorders of the blood-forming organs per se, but because recent studies of the giant cells in the inflammatory and neoplastic lesions of bones point increasingly to their origin from the same mesenchymal elements that are of intrinsic importance in the origin of primary hematopoietic disorders. It seems reasonable that the structure of such giant cells, falling as they do in a borderline zone between the fields of orthopedic pathology and hematopathology, should engage as much interest among hematopathologists as the reticulo-endothelial system does among orthopedic pathologists.

1. *Osteoclasts*.—These large, multinucleated cells make their appearance wherever bone is formed or undergoes a destructive process. They were first described by Kölliker³⁵ in 1872.

In tissue sections they are large multinucleated cells, measuring from 30 to 90 microns, with the longer diameter frequently parallel to a bone spicule but sometimes perpendicular to one. The nuclei are round or oval, are rather poor in chromatin, and possess a distinct nuclear membrane and one or two prominent, round, or rod-shaped (Fig. 46) nucleoli. The cytoplasm is abundant, deeply basophilic, granular or vacuolated, and provided with branching processes. Osteoclasts are usually found in Howship's lacunae, bays or grooves in dissolving bone (Fig. 46). Rustizky³⁶ said that they all contained calcium granules, but Maximow and Bloom¹⁸ found neither bone salts nor cell remnants in their cytoplasm.

In dry-fixed smears or imprints the many round or oval nuclei of the osteoclast resemble the pattern of histiocytic or reticulum cell nuclei, although, again as in sections, one to three prominent, deeply basophilic nucleoli are observed (Fig. 47). The nuclear pattern is characterized by small angular distinct chromatin particles irregularly distributed throughout the nucleus. Here there is chromatin-para-chromatin distinction and the nuclear membrane appears to be thinner than in section preparations. The cytoplasm immediately surrounding the nuclei is deeply basophilic and composed of a dense granular spongioplasm, whereas the more peripheral cytoplasm is composed of a background of slightly acidophilic hyaloplasm in which occasional flakes of basophilic spongioplasm appear. No azurophil granules are observed. Sabin and Miller³⁷ in their Fig. 5 show such an osteoclast in a fixed film of marrow, its cytoplasm filled with eosinophilic particles which stain like bone, and its nuclear configurations difficult to make out.

Origin: These cells arise from the mesenchymal elements of the bone marrow and periosteum, occasionally by fusion of osteoblasts.

Function: Most writers^{35, 37} attribute a phagocytic function to the osteoclasts, placing them in the group of foreign body giant cells because of their constant relation to the resorption or dissolution of bone and their disappearance when the resorption of bone ceases in a particular site.

Fig. 50.—Multinucleated giant cell in a section of malignant giant cell tumor of bone. Hematoxylin and eosin stain; $\times 2000$. AIP Neg. 97893.

Maximow and Bloom,¹⁸ as mentioned before, finding no phagocytic inclusions or bone salts within osteoclasts, hold that there is slight possibility of such cells possessing a phagocytic function.

Dameshek and Miller⁷ state that the polykaryocyte, precursor in a relatively uncommon type of megakaryocytic formation, is probably identical with osteoclast and forms the adult megakaryocyte by nuclear fusion. (Comparison should be made of their Fig. 5, our Figs. 10 and 47, and Rosenthal's¹⁶ Figs. 11 and 13.)

2. *Giant Cells of Bone in Osteitis Fibrosa Cystica Due to Adenoma of the Parathyroid Glands.*—Osteoclasts are numerous about the bony spicules in the characteristic lesions of osteitis fibrosa cystica (our Fig. 46). Giant cells, indistinguishable from osteoclasts, are likewise numerous in the fibrous connective tissue apart from the bony spicules or in and about foci of hemorrhage (Fig. 48). However, ingested red corpuscles are not observed within the cell bodies.

3. *The Giant Cells of Benign Giant Cell Tumor of Bone.*—Numerous giant cells are irregularly distributed through a benign stromal background of connective tissue in this condition. They have to all appearances the same morphologic characteristics as osteoclasts in tissue sections (Fig. 49), but they lack the relationship to Howship's lacunae. Their appearance in imprint preparations has not been described. Many modern writers consider these giant cells as osteoclasts or foreign body giant cells, not as tumor cells. Ewing,³⁵ however, emphasized giant cell proliferation as an essential feature of the lesion to which he referred as "osteoclastoma." Geschickter and Copeland^{38, 39} ascribe these giant cells to abnormal hyperplasia of osteoclasts, whereas Jaffe and associates⁴⁰ state that these giant cells are not osteoclasts and that they possess definite differences from osteoclasts.

Origin: These cells probably arise from mesenchymal elements⁴⁰ (histiocytes, reticulum cells); however, because these cells at times apparently form a portion of the lining of the blood vessels, an endothelial origin has been claimed, although it should be recalled that many of the simple vascular channels within bone are lined by littoral reticulum cells and not by simple endothelium. Foot³¹ tends to favor the idea of a reticulo-endothelial origin of these cells and notes that although the giant cells usually lie in clear spaces amid the reticular network, remnants of argyrophil substance may be found within their cytoplasm.

4. *The Giant Cells in Malignant Giant Cell Tumor of Bone.*—The stromal background of connective tissue is neoplastic both in structure and functions. The multinucleated giant cells irregularly distributed throughout these lesions (Fig. 50) present few or no characteristic features which distinguish them from osteoclasts. Their appearance in dry-fixed impressions has not been described. However, Jaffe and associates⁴⁰ observed that the nuclei of these giant cells actually may share in the atypism of the stromal cells (their Fig. 4) and become swollen and large, out of proportion to cell size. It is important to note that these cells are almost always absent in the metastatic lesions of this tumor. There is but one case in the files of the Institute of Pathology in which the same "benign" appearing, multinucleated giant cells were found in an extension or

spread from the tumor in the ulna to an epitrochlear lymph node. Our Fig. 50 is from the ulnar lesion in this case.

5. *Giant Cells in Osteogenic Sarcoma.*—In many instances tumor giant cells of all sizes and shapes are abundant in this lesion. These tumor giant cells are to be distinguished both from the foreign body giant cells which may also be present, particularly about areas of hemorrhage, and from the osteoclasts in focal areas of bone resorption. Depicted in Fig. 51 is a giant cell of this reactive type from an osteogenic sarcoma. The tumor giant cells of osteogenic sarcoma may be giant mononuclear forms (Fig. 52), polymorphonuclear forms (Fig. 53), or multinucleated forms (Fig. 54). The extremely large size of the nuclei may be appreciated at once by comparison with those of any of the osteoclasts previously described (Figs. 47 and 48). The nuclei are bizarre in shape, frequently hyperchromatic with coarse chromatin clumps in evidence (Figs. 52 and 54). One or more giant, round or irregular, acidophilic nucleoli are present. The cytoplasm may be scant or abundant and shares in the cytoplasmic type of the more numerous, surrounding, smaller neoplastic cells as to intrinsic structure and nature of intercellular substance. Bizarre, atypical, occasionally multipolar mitoses are to be found in these cases. The morphologic characteristics of the cell in dry-fixed preparations have not been described.

Origin: Tumor giant cells arise by abnormal mitoses in or fusion of tumor cells. Ultimately they arise from the embryonic or mesenchymal elements capable of bone formation.

6. *Giant Cells in Ewing's Tumor of Bone.*—Ewing³⁵ mentioned an occasional report of the presence of giant cells in the tumor known by his name. This observation is of importance to the hematologist in view of Piney and Hamilton-Paterson's⁴¹ description of giant, histiocyte-like elements, which they call "dysmorphokaryocytes." These cells, which possess indented nuclei and irregular hyaline cytoplasm, may be found scattered among the cells of the sternal marrow prior to any other indication of the spread of the tumor from its primary state. No example of this cell type was to be found in the material which we have studied. Rohr¹⁰ states that in his hands sternal punctures have revealed no sure signs of malignant changes in cases of this disease.

Origin: Ewing³⁵, p. 368 suggested as the cellular origin of his tumor "the perivascular endothelium," which to him represented a perivascular cell with mere endothelial potentialities. Oberling and Raileanu⁴² and more recently Stout⁴³ would prefer to designate this tumor as a variant of reticulum cell sarcoma on the basis of the demonstration of reticulum cells as integral parts of some of them. Stout does not mention the presence of giant cells in this tumor.

7. *Giant Cells in Other Conditions.*—Giant cells identical with or similar to the osteoclast or the foreign body type may also be found in healing fractures, exuberant callus formation, acute and chronic osteomyelitis, rickets, osteomalacia, osteogenesis imperfecta, osteochondritis desiccans, Paget's disease, angioma, fibrous dysplasia of bone, medullary fibroma, xanthofibroma, and medullary chondroma, to mention but a few conditions affecting the soft tissue of the bone and not ordinarily the province of the hematopathologist.

G. PLASMACELLULAR GIANT CELLS.—

1. *Multinucleated Plasma Cells*.—Multinucleated plasma cells usually are present wherever the ordinary mononuclear plasma cells are to be found in the blood-forming organs. They were described first by Cajal (Michels⁴⁴). They are not uncommon in practically any of the subacute and chronic inflammatory reactions as well as in agranulocytosis and aplastic anemia (Rohr's¹⁰ Figs. 22 and 71).

In stained tissue sections they are smaller than most giant cells, being about 20 microns in diameter, round, oval or elongated, and possessing from 2 to 4 discrete nuclei usually placed near the periphery of the cell. At times the nuclear pattern may be rather characteristic, consisting of coarse particulate chromatin arranged about the lining of the nuclear membrane in a spokelike fashion so as to present Pappenheim's "radkern" effect; in numerous instances the pattern may merely resemble the lymphocytic nuclear pattern with somewhat coarser features. A nucleolus usually is present. The cytoplasm is occasionally vacuolated and is deeply basophilic, save for a central pale area near the nuclei which is a rather specific characteristic. When stained with Pappenheim's methyl green-pyronin the cytoplasm is a brilliant red whereas the chromatin is a greenish purple (Slider and Downey²).

In dry-fixed impressions the nuclei are round or oval and possess a chromatin pattern midway between those of the reticulum cell and the lymphocyte, in that the chromatin granules are arranged in coarse clumps but present chromatin-parachromatin distinction (our Fig. 55). Characteristically in these preparations the "hof" or central light area has disappointingly vague borders and the cytoplasm is found to consist of closely packed, deeply basophilic granules or flakes at the periphery; these become increasingly scant as the center of the cell is approached, allowing more and more of the pale pink hyaloplasm to show through in the central cytoplasmic area. These cells are devoid of azurophil granules.

Origin: These cells arise from pre-existing plasma cells by amitotic nuclear division without cytoplasmic division (Michels⁴⁴) ultimately from reticulum cells or lymphocytes.

2. *Multinucleated Myeloma Cells*.—Because of our lack of knowledge as to the function of the plasma cell, it is difficult to affirm or deny Rohr's¹⁰ contention that multiple myeloma represents a malignant tumor of the reticulum. However, certain differences in structure between the cells of this and the preceding group can be noted at times.

These cells as seen in tissue sections are usually merely binucleate, but 3 to 8 or even more discrete nuclei have been observed. They may resemble plasma cells with their round, lymphocyte-like, peripheral nuclei and abundant basophilic cytoplasm with a central light area (Fig. 56), or they may present all transitions to larger cells with more abundant colorless or slightly acidophilic cytoplasm, the pale perinuclear area thus being lost. Ewing²⁵ observed mitoses in these cells but less frequently as they approached the plasma cell type. According to Jones,²² myeloma cells do not take the specific methyl green-pyronin stain described for plasma cells.

In dry-fixed preparations the discrete nuclei may vary in size within a single cell and in different cases may show nuclear patterns of the reticulum cell, the plasma cell, or the lymphocyte. These cells may possess as many as from 5 to 8 nuclei which may be plasmacellular in type, but each nucleus contains a moderate-sized, dark blue nucleolus. The cytoplasm may contain less basophilic spongioplasm than the cell of Fig. 55 and a few scattered azurophil granules may be found within the central cytoplasmic area. In Fig. 57 the pattern of the two nuclei resembles that of a reticulum cell with prominent basophilic nucleoli, and the cytoplasm is composed of diffusely granular basophilic spongioplasm. Further illustrations of giant cells of this group are to be found in Rohr's¹⁰ monograph (his Fig. 116) and in a recent work by Erf and Herbut,⁴⁵ who further attest to the value of the dry-fixed preparations as an adjunct to tissue sections in cytologic diagnosis.

Origin: Multinucleated myeloma cells may arise from the myeloblast (Fleischhaecker and Klima⁴⁶), and from the lymphocyte (Ewing³⁵) or from the reticulum cell (Rohr¹⁰). Recently, Herbut and Erf⁴⁷ have described megakaryocytoid and lipoblastic giant myeloma cells in cases of multiple myeloma.

3. Giant Cells of Plasma Cell Leukemia.—Plasma cell leukemia is generally regarded as closely related to multiple myeloma (Lubarsch,⁴⁸ Moss and Ackerman,⁴⁹ Patek and Castle,⁵⁰ Jackson and associates⁵¹). Giant cells are less frequent than in multiple myeloma and, when they occur, rarely possess more than two nuclei (our Fig. 58). Such a cell from a dry-fixed bone marrow aspirate is depicted in Fig. 58. In structure it tends to resemble ordinary reactive multinucleated plasma cells more closely than the comparable myeloma cell. Patek and Castle⁵⁰ using the same technique depict a similar cell (their Fig. 2) and Osgood and Hunter⁵² portray in colors (their Fig. 8) just such a cell with one of the nuclei very large and irregular and the cytoplasm containing azurophil granules.

H. GIANT CELLS IN SYSTEMIC DISTURBANCES INVOLVING LIPIDS.—

1. Giant Cells in Niemann-Pick's Disease.—The giant cells in Niemann-Pick's disease are relatively rare, the mononuclear type predominating. According to Pick⁵³ these cells "include one or two small nuclei, occasionally many." The central cell of our Fig. 59, as seen in tissue section, contains three such nuclei. The nuclei are round or oval, peripheral and discrete, and the chromatin particles are small but numerous, so that the pattern is similar to that of the nucleus of a reticulum cell or a histiocyte. The abundant cytoplasm con-

(For legend, see opposite page.)

sists merely of small and large, round vacuoles with thin intervening septa. The vacuoles are clear with ordinary staining methods, stain poorly (depending on mordant) with Nile blue and sudan III, but stain with the Smith-Dietrich method. The cells contain a phosphatide, sphingomyelin (Klenk⁵⁴). For further cytologic detail and the histogenesis of this cell type the reader is referred to Bloom's⁵⁵ detailed monograph. The characteristics of these cells in dry-fixed preparations are well illustrated in photomicrographs of Piek⁵³ (his Fig. 1), in which the cells from the spleen contain a dense homogeneous central cytoplasm with the typical vacuoles peripherally situated, and of Rowland⁵⁶ (his Figs. 47 and 48), in which cells from the spleen and bone marrow show a more diffuse distribution of the vacuoles.

2. *Giant Cells in Gaucher's Disease.*—Giant cells are rather frequently found in Gaucher's disease although the mononuclear type still predominates. Such Gaucher cells are multinucleated. As seen in tissue sections, the discrete nuclei have reticulum cell or histiocytic characteristics although the chromatin content is more conspicuous. The cytoplasm stains poorly with sudan III, Smith-Dietrich, or Nile blue; however, Mallory's aniline blue, connective tissue stain reveals a cytoplasm filled with a dark blue fibrillar substance, weblike in arrangement, in contrast to the honeycombed or foamlike appearance of other lipid-containing cells. In fact, the cytoplasm of Gaucher cells is frequently spoken of as being wrinkled. Piney and Hamilton-Paterson⁴¹ state that the fibrils of these cells may be brought out by silver impregnation. The appearance of these cells in tissue sections is well portrayed by Mandelbaum and Downey.⁵⁷ Most authors state that the cells contain the cerebroside, cerasin, originally described by Lieb.⁵⁸

The appearance of multinucleated Gaucher cells in dry-fixed preparations is similarly characteristic. The cells measure more than 50 microns in diameter. The oval or round discrete nuclei are relatively small and resemble reticulum cell nuclei, save that the irregular angular pieces of chromatin are coarser, although the chromatin-parachromatin distinction is preserved. A single, small, round basophilic nucleolus is present in each nucleus. Basophilic fibrils are to be found embedded in the colorless or faintly basophilic cytoplasm (our Fig. 60). As degeneration sets in, however, vacuoles may also appear in the cytoplasm of these cells.

3. *Giant Cells in Hand-Schüller-Christian Disease.*—The majority of the giant cells seen in the xanthomatous lesions of this disease are lipid-containing but otherwise ordinary foreign body giant cells. The cytoplasm stains well with sudan III. The cells contain cholesterol and cholesterol esters as described originally by Pinkus and Piek⁵⁹ in symptomatic xanthomatoses. A more spectacular type of giant cell called the Touton giant cell⁶⁰ (Fig. 61) is occasionally found. This cell presents a rim of closely spaced discrete nuclei of the histiocytic type about an area of dense, homogenous, acidophilic cytoplasm. The ring of nuclei in turn is surrounded by an abundant, peripheral, foamy cytoplasm. It must be emphasized that cells of this type are not specific for Hand-Schüller-Christian disease but may be found in the so-called secondary xanthomatoses as well; in fact, the cell depicted in Fig. 61 was found in an area of fatty degeneration within a kidney, the seat of chronic pyelonephritis. The structure

of the so-called nonspecific lipoid histiocytes is apparently not well known; Paseyro²¹ (his Fig. 113) depicts such a large vacuolated cell from the bone marrow in a case of diabetic xanthomatosis. For further interesting details the reader is referred to the monograph of Thannhauser and Magendantz²¹ upon this subject.

4. *Normal Fat Cells*.—Normal fat cells within the blood-forming organs present few structural features that are of differential significance as seen in tissue sections. However, in dry-fixed preparations these large cells become flattened and distorted; they measure more than 60 microns in diameter and are usually round with an eccentric nucleus of the histiocytic type and an abundant colorless cytoplasm. As the cell body is broken up the cytoplasm takes on a wrinkled appearance and a faint basophilic tinge; at the same time numerous small vacuoles appear, particularly about the nucleus (our Fig. 62).

5. *Nonspecific, Fat-Containing Foreign Body Types of Giant Cells*.—These cells are not uncommonly found in the blood-forming organs, particularly the lymph nodes, under many and diversified conditions (Fig. 63). They are frequently seen in or about reactive or degenerative processes.

I. GIANT CELLS IN MEASLES (Warthin-Finkeldey Giant Cells).—These giant cells are variously found in the germinal centers and surrounding lymphoid tissue of the abdominal lymph nodes, spleen, tonsils, appendix, or lymphoid tissues of the respiratory and gastrointestinal tracts, usually in the prodromal period of measles. Giant cells were first observed in measles by Alagna⁶² who believed they somewhat resembled megakaryocytes. Warthin⁶³ and Finkeldey^{64, 65} gave the first accurate descriptions of this specific giant cell type. They are large syncytial multinucleated giant cells containing from 5 to 50 or more nuclei. The overlapping nuclei are generally arranged in a grape-like or mulberry-shaped cluster bordered by a scant rim of eosinophilic cytoplasm. In the germinal and reaction centers the nuclei tend to be of the pale, vesicular, reticulum cell type (Fig. 64), with several small- or moderate-sized nucleoli. In the surrounding lymphoid tissue are numerous similar cells (Fig. 65) with nuclei containing coarser chromatin particles resembling plasma cell nuclei. The nuclei in this latter cell type are somewhat more diffusely arranged, but the cytoplasm remains as a scant acidophilic border. Warthin⁶³ found no intracellular microorganisms or inclusions within the cytoplasm of these cells, but Hathaway⁶⁶ described them as being phagocytic.

Origin: Warthin⁶³ regarded these giant cells as derived from cells of the lymphoblast type. Mulligan⁶⁷ concluded that they arose by a "polynuclear abnormal development of the stem cell." The consensus is that they arise by amitotic division of reticulum cells, mesenchymal cells, plasma cells, or lymphocytes or by fusion of lymphocytes (Corbett⁶⁸). In Fig. 66 is depicted the origin of such a cell in a distorted, reactive, multinucleated reticulum cell.

J. FOREIGN BODY TYPES OF GIANT CELLS (LANGHANS' GIANT CELL).—In 1868 Langhans⁶⁹ described the cell in tuberculosis which now bears his name. It is a multinucleated giant cell having from 2 to more than 1,000 round or oval nuclei. In tissue sections the nuclei contain fine chromatin particles and a small

nucleolus or two; they resemble the nuclei of histiocytes or reticulum cells. By usage "Langhans' type giant cell" has come to designate the type of cell with its nuclei arranged in a ring near the periphery of the cytoplasm. The cell outline may be round, oval, irregular, or stellate. The cytoplasm itself is slightly acidophilic and may be finely granular or homogeneous. At times ingested inclusions may be present, that is *Mycobacterium tuberculosis* may be demonstrated by acid-fast methods. Actually, however, Langhans not only described the cells with the peripheral ring of nuclei but also those with nuclei at one or both poles of the cell body, scattered diffusely throughout its substance or placed centrally. This group of cells without the ring of nuclei is referred to as the foreign body type of giant cells by modern writers. Actually both groups are nonspecific. In infectious granulomas the so-called Langhans' type may be more frequently observed, whereas the foreign body type of nuclear arrangement is more likely to be found about inert foreign substances, although this is by no means invariable.

Foreign body giant cells arise by fusion of individual macrophages (histiocytes) or by amitotic division of their nuclei without constriction of the cell bodies. The macrophages in turn arise from lymphocytes and monocytes which have migrated from the blood or from cells of the fixed connective tissues possessing phagocytic abilities. The blood-forming organs, abounding as they do in fixed connective tissue cells with the ability of becoming phagocytic, usually draw upon this source for production of their phagocytic giant cells. It is beyond the scope of this review to include all of the affections of the blood-forming organs in which the presence of the various foreign body giant cells may be observed; however, some of them are herein listed:

1. Tuberculosis (Langhans⁶⁹).

2. Syphilis, especially in the secondary stage (Michelson⁷⁰), but not confined to that stage.

3. Actinomycosis (Forbus⁷¹ in his Fig. 349 depicts a rod-shaped sulfur granule of *Actinomyces bovis* being ingested by a foreign body giant cell).

4. Leprosy. Langhans' and foreign body giant cells may be present in affected lymph nodes (our Figs. 67 and 68). With acid-fast techniques some of these cells are found to contain large numbers of *Mycobacterium leprae* arranged as packets and globi (Fig. 67). An additional finding, although not specific for leprosy, is the peculiar structures occasionally observed within the cytoplasm of such cells, called "asteroids" (Fig. 68). These were first described by Wolbach.⁷² They are embedded in a round, pale staining area of the cytoplasm and consist of a central dense zone from which radiate from 10 to 15 or more sharp or blunt spindles, the entire structure being more or less star shaped. Asteroids are usually acidophilic and have been observed in the giant cells of tuberculosis, Boeck's sarcoid, and histoplasmosis as well as of leprosy, to mention but a few.

5. Lymphogranuloma venereum (lymphopathia venereum). In Fig. 69 is depicted a giant cell of the Langhans' type in the zone of palisaded histiocytes about a typical stellate abscess in an inguinal lymph node in this disease (Ash and Spitz⁷³).

PLATE XV

Fig. 69.—Langhans' type giant cell in section of inguinal lymph node in lymphogranuloma venereum (lymphopathia venereum). Hematoxylin and eosin stain; X2000. AIP Neg. 97620.

Fig. 70.—A portion of a large foreign body giant cell containing a Schaumann body in section of lymph node in Boeck's sarcoid. Hematoxylin and eosin stain; X2000. AIP Neg. 97619.

6. Visceral leishmaniasis, Kala-azar (Meleney⁷¹).

7. Boeck's sarcoid (Schaumann⁷²). Foreign body giant cells are frequently observed in the granulomatous lesions of this disease. Rare cells may contain a large, laminated, deeply basophilic, roughly spherical structure called the "Schaumann body" (Fig. 70). These bodies are rather specific for Boeck's sarcoid although similar structures are occasionally to be found in other conditions.

8. Coccidioidomycosis. Shown in Fig. 71 is a giant cell which contains the causative organism, *Coccidioides immitis*, a nonbudding cell form undergoing endosporulation. Note the thick, double-contoured capsule.

9. Paracoccidioidal granuloma, South American blastomycosis (Moore⁷³).

10. Histoplasmosis. In Fig. 72 is depicted an irregular type of foreign body giant cell in which numerous organisms are to be found. *Histoplasma capsulatum* appears as a very small yeastlike cell with a prominent nucleus and a thick refractile capsule. The small portion of free cytoplasm immediately above the giant cell in Fig. 72 likewise contains several such organisms.

As mentioned in the section on the giant cells in Hodgkin's disease, it should be kept in mind that nonspecific and merely reactive foreign body giant cells may occur in lymphomas and related afflictions of the reticulo-endothelial system.

For further details of the morphology and occurrence of foreign body giant cells in specific diseases the reader is referred to the excellent monographs of Haythorn¹ and Ash and Spitz.⁷³

K. MISCELLANEOUS GIANT CELLS AND STRUCTURES RESEMBLING GIANT CELLS.—

1. *Nonspecific Reactive Giant Cells.*—Frequently in the nonspecific subacute and chronic inflammations affecting particularly the lymph nodes and spleen, a few reactive forms of giant cells are found of which little previous mention has been made in the literature. They consist of small foreign body giant cells with a few irregularly situated histiocytic nuclei, or they are polylobular mononuclear forms (Fig. 73), probably representing a reactive multilobulation of the reticulum cell nucleus. Their nuclei have small basophilic nucleoli and varying amounts of granular chromatin. The cell outline is usually irregular and the faintly acidophilic cytoplasm is not remarkable. Occasionally many fat-con-

(For legend, see opposite page.)

taining vacuoles are to be found within the cell body (Fig. 63). These types are of importance because they have at times been confused with megakaryocytes or with the giant cells of Hodgkin's disease and reticulum cell sarcoma.

2. *The Giant Cells in Brucellosis.*—In certain relatively rare reactions of the blood-forming organs to brucella, particularly *Brucella melitensis*, the histiocytic and reticulum cell reaction may present nonspecific pleomorphism similar to that described in the preceding paragraph. Represented in Fig. 74 is just such a type of giant cell in the lymph node from a case of brucellosis proved by both blood cultures and recovery of the organism after animal inoculation. These cells have been spoken of as simulating the cells of Hodgkin's disease. However it is apparent that the nuclei of the giant cells of brucellosis are like those of nonspecific histiocytes or reticulum cells, with small although circumscribed basophilic nucleoli.

3. *The Giant Cells in the Lymph Nodes of Disseminated Lupus Erythematosus.*—Recently Fox and Rosahn¹⁷ have described a type of giant cell frequently found in the lymph nodes in cases of disseminated lupus erythematosus. It is superficially somewhat like a megakaryocyte, possessing one or two large multilobular nuclei with a greater chromatin content than the customary reticulum cell nucleus (Fig. 75). Unlike a megakaryocyte, however, it lacks evidence of pseudopodial platelet formation, its cytoplasm being composed of a homogeneous, pale, or acidophilic substance.

4. *Scavenger Cells.*—Occasionally large phagocytic mononuclear macrophages which have ingested numerous nuclear remnants (Fig. 76) may be mistaken for unusual giant cell forms.

5. *Capillary Cross Section.*—Another structure which may be confused with abnormal giant cell types is the specially constructed blood capillary of the lymphatic tissue of the lymph nodes and the appendix when it is viewed in cross section (Fig. 77). These capillaries are lined by a single layer of cuboidal endothelial cells instead of those of the usual pavement cell type. Lymphocytes are frequently found migrating through the walls of these structures, which thus serve as a mode of egress for the lymphocytes in addition to the efferent ducts. When, as is frequently the case, the lumen is found to contain red corpuscles as well as lymphocytes, the true nature of the structure is apparent at a glance. In inflammatory reactions, however, the cuboidal cells may become swollen so as to occlude the lumen, making identification difficult unless serial sections are available; in these the identity of the structures is readily apparent (Maximow and Bloom¹⁸).

COMMENT

The structure of the giant cells of the blood-forming organs in both physiologic and pathologic processes has been presented in atlas form. Attention of the hematologist is directed to variations of the giant mesenchymal structures of the hematopoietic organs in conditions not ordinarily of prime hematologic interest, for the reason that such affections are of the same stromal site or origin as are many of the blood dyscrasias. The use of dry-fixed smears or impression

preparations of the blood-forming organs in conjunction with tissue sections affords another source of information regarding structural characteristics of many giant cell types.

It is hoped that the collection of photomicrographic representations of the many giant cell types within the scope of a single article will provide an opportunity for ready comparison of both related and unrelated giant cell forms and will serve as an aid in the determination of the nature and degree of such relationships or differences.

MITOCHONDRIA AND THEIR RELATION TO THE SO-CALLED HYALOPLASM

OLIVER P. JONES, PH.D.
BUFFALO, N. Y.

INTRODUCTION

DURING the past fifteen years considerable morphologic evidence has been collected which indicates that genuine megaloblasts have no role in normal erythropoiesis.^{1, 2} But megaloblasts do, however, play the major role in the pathologic erythropoiesis which occurs in bone marrow from patients with a liver principle deficiency anemia. Before arriving at these conclusions, it was necessary to study material similar to that which Doan and associates³ used while formulating their theory for avian and mammalian erythropoiesis. Because of the studies of Sabin⁴ in 1921 on vitally stainable granulation in erythroblasts, blood drawn from chick blastoderms on the second and third days of incubation was considered the best single source of cells which Doan and associates would accept unequivocally as megaloblasts. In my studies of the blood from these chick blastoderms it was considered desirable not only to study it vitally according to Sabin's method, but also to employ Doan and associates' supravital technique and to check Sugiyama's⁵ findings with Wright's stain.

Although my observations on chick erythroblasts stained vitally with neutral red confirm those made by Sabin, observations made on Wright stained dry films did not correspond to either Sabin's or Sugiyama's description. First, the nuclei were not as empty or devoid of structure as described by Doan and associates, nor as poorly preserved as illustrated by Sugiyama. Second, the cytoplasm of these primitive red blood cells had much more structure than described by Sabin and it differed in degree from the cytoplasm described and illustrated by Sugiyama. The thing which attracted my attention was the presence in the cytoplasm of pale or yellowish areas of hyaloplasm, sometimes discrete, not unlike those described by Downey⁶ in cells from certain cases of leukemic reticulo-endotheliosis. These observations alone did not seem to be so important until similar cells stained supravitaly with either janus green or pinacyanol were found to have a distribution of mitochondria practically identical with the areas of hyaloplasm as seen in dry fixed smears. Because of the apparent high degree of correlation between these structures seen in cells prepared by two different methods, it was tentatively concluded that the so-called hyaloplasm represented the negative images of mitochondria. Due to an interest in the placental transfer of antipermeious anemia principle⁷ and the development of a presumptive test for it,⁸ studies made originally on chick primitive erythroblasts were carried over to similar cells in the yolk sac of the eleven-day rat embryo. Normally these yellowish areas or flecks in the basophilic cytoplasm are distributed so as to fall into three main categories,

From the Department of Anatomy, University of Buffalo School of Medicine.
Research was aided by the Dr. Grant T. Fisher Fund.

namely, diffuse, perinuclear, and a juxtannuclear clump. The latter was of particular interest since the administration of liver extract, desiccated hogs' stomach, or synthetic folic acid produced an increase in the number of cells having a juxtannuclear clump of the cytoplasmic pale areas in dry fixed material and of the mitochondria in the supravital material.

The present paper describes results which represent the termination of an extended period of observation and the beginning of an analysis of the cytoplasm with various techniques applicable to the material studied.

METHODS

Twenty dozen chicken eggs were incubated for periods ranging from two to nine days. Blood was drawn from the blastoderms and studied according to the techniques described by Sabin⁴ and Sugiyama.⁵ Pinaeyanol⁹ was usually the dye use for supravital technique, but janus green and neutral red were also used, especially for the studies on chick blood cells.¹⁰ Throughout the course of investigating several related problems, 4,187 eleven-day rat embryos were obtained from seventy-nine control and 308 test pregnant Wistar rats. Blood from the yolk sac¹¹ was studied by means of various techniques. In supravital studies, amniotic fluid was withdrawn by means of a fine capillary pipette before delivering the rat yolk sac. A drop of this was placed on a specially prepared slide and yolk sac swished around in it. Then the preparation was covered and sealed with petroleum jelly. Although blood cells from embryos whose mothers received various antianemic substances were studied as the occasion arose, only observations on normal yolk sac blood are considered in this article. Dry films of blood from 1,657 embryos were stained with the May-Grünwald-Giemsa combination of Pappenheim within six hours after they were made. Permanent mitochondrial preparations were made from dry films of both embryonic chick and rat blood cells. The former were fixed and stained according to Schridde's¹² original technique, with the exception that differentiation was carried out in 1 per cent methyl green rather than picric acid alcohol. Practically all of the mitochondrial preparations of embryonic rat blood cells were made by adapting the standard Bensley-Cowdry technique¹³ to this material. Cover slip preparations were dried rapidly and placed immediately in either Regaud's formalin bichromate or acetic osmic bichromate for eighteen to twenty-four hours. They were washed in tap water for two or three minutes followed by a brief bath in distilled water. The use of permanganate and oxalic acid was unnecessary. The cover slip preparations with the fixed film directed upwards were placed on slides to facilitate handling while staining with aniline acid fuchsin. Heat was applied for ten seconds and the preparation allowed to cool. This was repeated two or three times. Either methyl green or Wright's stain applied for ten to fifteen seconds was used for differentiation and counterstaining. Dehydration was accomplished by rapidly passing the cover slips through two changes of absolute alcohol followed by xylene. The distribution and localization of lipid material was studied with the aid of sudan black, which was introduced by Lison¹⁴ and later employed by Baker¹⁵ for the study of Golgi element. Freshly dried cover slip preparations were placed in Baker's formal-calcium fixative for eighteen to twenty-four hours. After washing in distilled water for one or two minutes, they were passed through 50 and 70 per cent alcohol and stained in a saturated solution of sudan black in 70 per cent alcohol for ten minutes. Cover slips were placed with the fixed smears facing downward in the sudan black in order to prevent dye particles from collecting on cells. Small glass rods or a metal paper clip were used to elevate the cover slips from the bottom of the staining dish and thereby permit an even distribution of stain. Excessive amounts of the dye were extracted by passing the preparation through three changes of 50 per cent alcohol for exactly ten seconds in each change of alcohol. They were then washed in distilled water for about two minutes and mounted in glycerol.¹⁶ No counter stain was used. The presence of vitamin A was detected by using the Carr-Price reagent of 30 per cent antimony trichloride in chloroform.¹⁷ Cover slip preparations, which had been kept in the dark, were inverted on a clean slide and two parallel

edges were sealed with petroleum jelly. This aided in channeling the reagent and prevented the cover slip from moving when the immersion lens was focused. The preparation was then examined under low power for a suitable field of primitive erythroblasts which when found was examined with the oil immersion lens. The reagent was permitted to flow beneath the cover slip by capillary attraction. The presence of vitamin A was indicated by a fugitive light greenish blue color reaction.

Phase microscopy¹⁸ has been a great aid in this problem. The optical differentiation of cytoplasmic structures having small differences in their optical path was made possible by selecting an oil immersion lens with the proper diffraction plate. Bright contrast was obtained with a 1.8 mm. objective, $0.2A + 0.25 \lambda$, and dark contrast with 1.8 mm. objectives, $1.0B-0.25 \lambda$ and $2.3B-0.33 \lambda$. Unstained dry films were inverted on a drop or two of either Baker's formol-calcium or 10 per cent formalin and ringed with petroleum jelly. Such preparations have remained in good condition for two months. After studying cells with phase microscopy, it was then possible to mark them for restudy with a bright field microscope following Wright's stain or Baker's formol-sudan black. Oil and petroleum jelly were removed by camel's hair brush moistened with xylene. Cover slip preparations were washed briefly in distilled water, dried, and stained with Wright's stain. They were again washed briefly in distilled water, dried in air, cleared in xylene, and mounted in clarite. Both bright- and dark-contrast phase microscopy were used with sudan black preparations. Although dark contrast was used in combination with the supravital technique, preference was given to studies of unstained dry films with bright contrast phase microscopy. The combination of dark contrast phase microscopy and sudan black brought out more detail than either technique alone. All of these studies were done with a Spenceer research microscope.

OBSERVATIONS

A. Embryonic Chick Blood Cells.—

1. *Dry Films of Blood From Chick Blastoderms Incubated Two Days:* This material should be of interest to all students of the megaloblast-normoblast problem since, according to Doan and associates³ and Sabin,⁴ practically all of the cells present are megaloblasts, in the sense of their definition. However, no matter how intriguing this phase of the problem may be, it must not detract from our present interest in the cytoplasm. Some of these cells are illustrated on Plate I and designated as primitive erythroblasts according to Maximow.¹⁹ Regardless of whether Wright's stain or May-Grünwald-Giemsa is used, one of the most striking characteristics is the very basophilic cytoplasm which agrees with the observations made by Doan and associates³ and Dawson²⁰ but not with those of Sugiyama⁶ who described it as having a reddish tinge. Another constant characteristic of this basophilic cytoplasm is that it is not uniform and homogeneous, contrary to Doan and associates³ universal description for such cells. It is mottled with light areas of what Pappenheim²¹ called hyaloplasm (paraplasm). These areas are neither uniform in their size and shape, nor their distribution. For example, in cell 1, *a*, Plate I, there are faint filamentous light areas, while in cell 1, *b*, there is a definite juxtanuclear light area in addition to others scattered throughout the cytoplasm. The juxtanuclear area of cell 1, *b*, may be what some authors have called the region of the centrosphere, which according to Dawson²⁰ is indistinct but according to Sugiyama⁵ appears as a clear red spot. At no time were large perfectly clear spots lacking substance found as described and illustrated by Sugiyama. Such an area in his Fig. 4 was in all probability an artifact.

The nuclei of these primitive erythroblasts have one or two large well defined nucleoli. They may be round or irregular. The nuclear chromatin and its characteristic pattern, however, are something which escaped the attention of Sabin,⁴ Doan and associates,³ Sugiyama,⁵ and Dawson.²⁰ It is very definitely not pale, scanty, and obscure as these authors have reported. To the contrary, the nuclear pattern is quite distinctive and is not identical with that of any cell normally found in the bone marrow. The chromatin is arranged in more or less angular particles varying in size. They are not as uniform in size and distribution as those of genuine megaloblasts of pernicious anemia bone marrow during relapse.^{1, 2, 22} There is a sharp demarcation between the chromatin and parachromatin (basal- and oxychromatin). Although the parachromatin is conspicuous in some cells, it never exceeds the chromatin in amount. Some of the chromatin particles have delicate strands connecting them. There is usually a marked tendency for it to concentrate in the vicinity of the nucleoli. Sugiyama's⁵ Fig. 8 does a great injustice to these cells.

2. *Supravital Preparations of Blood From Chick Blastoderms Incubated Two Days:* Either janus green or pinacyanol was used for these studies. In general, the mitochondria were either rod or coccoid forms like those described by Doan and associates³ for the rabbit and Sugiyama⁵ for the chick. Their number varied from 28 to 57. In addition to these there were also occasional filamentous forms which did not stain as intensely as the other forms. In no instance were the long filaments the only type of mitochondria present as reported by Dawson.²⁰ In many cells the mitochondria were scattered throughout the cytoplasm but in others they had a very definite perinuclear and juxtannuclear arrangement not unlike the clear areas shown in cell 1, b, Plate I. Their position seemed to be relatively stable since they would maintain their perinuclear distribution even though the cells were flattened and made to move by gentle pressure on the cover slip. They really gave the impression of clinging to the nucleus as Cunningham and Tompkins²³ have described for other cells. In dead or damaged cells, the mitochondria would move and oscillate, indicating a change in the cytoplasm from a gel to sol state.

After preparations were studied with a bright-field microscope, they were then examined with dark-field illumination; the deep purple or dark blue mitochondria stained with pinacyanol appeared orange and the green mitochondria stained with janus green appeared reddish. However, the most important finding was that not all of the mitochondria had been stained selectively. The number of unstained refractile mitochondria varied from 1 to 6 per cell. No counts were made to determine the relative proportion of cells with all of their mitochondria stained. It was first thought that the concentration of the dye, its distribution on the slide, or the duration of exposure might have something to do with the nonstaining of some mitochondria, but subsequent studies on the rat primitive erythroblast have lead to the conclusion that mitochondria within a single cell differ in their composition.

3. *Permanent Mitochondrial Preparations of Blood From Chick Blastoderms Incubated Two Days:* After the previously stated observations were made it

was tentatively concluded that the light areas, as seen in dry films of primitive erythroblasts stained with the usual hematologic dyes, represented negative images of mitochondria. Investigations of this problem along more critical and analytical lines had to be postponed for about seven years. However, these observations have now been verified and another method of study was introduced. It was felt that since all mitochondria do not stain supravitaly, and this reaction is probably due to the presence of a proteolytic enzyme,²⁴ one of the more specific techniques should be applied to this material. Only moderate success was obtained when Schridde's modification of Altmann's technique was used.¹² The cells were rounded up and the distribution of mitochondria was not readily made out. Then too, a great many cells were lost from the cover slips. Both of these difficulties were overcome when the first part of Freifeld's technique²⁵ was used, namely, the rapid drying of films or imprints before immersion in the fixing fluid. It is understood that this means drying in air at room temperature until the films appear dry. After examining these preparations and noting the clear-cut mitochondrial distribution as that in cells 2, a,

PLATE I

All cells were photographed at the same magnification of 1850 diameters. Cell X is a red blood cell from the maternal placental circulation to be used as a comparison of size. Nuclei of most cells are out of focus in order to bring out cytoplasmic detail. With the exception of cells 1 and 2, all cells are primitive erythroblasts from the yolk sacs of eleven-day rat embryos.

1, Blood from chick blastoderm after two and one-half days incubation. Wright's stain. Cytoplasm is quite basophilic. Light areas of the so-called hyaloplasm vary in shape and distribution. Cell 1, a, has filamentous clear areas; cell 1, b, a juxtanuclear clump; and cell 1, c, a diffuse distribution.

2, Blood from chick blastoderm after two and three-quarter days incubation. Modified Schridde's mitochondrial technique using methyl green for differentiation and counterstaining. Most of the mitochondria tend to be coccoid shaped but some short plump rods and filaments were present. In cell 2, a, the mitochondria have a diffuse distribution. Faint filaments are present in the lower portion of the cytoplasm. Cell 2, b, has a perinuclear distribution of mitochondria.

3, May-Grünwald-Giemsa stain. Cytoplasm is deeply basophilic. This cell is of particular interest because there are filamentous areas of the so-called hyaloplasm. Some of these areas are quite curved and may appear horseshoe shaped like that shown in the lower left portion of the cytoplasm.

4, May-Grünwald-Giemsa stain. Cytoplasm is quite basophilic with a more or less diffuse arrangement of yellowish areas of the so-called spherical area in the upper left portion of the cytoplasm. See text for discussion of its probable nature.

5, May-Grünwald-Giemsa stain. Most of the cytoplasm is very basophilic and fairly homogeneous. Note that the light areas of so-called hyaloplasm have a perinuclear arrangement. The small, dark rodlike structure at the upper margin of the cell is a piece of dust.

6, May-Grünwald-Giemsa stain. The nonmitotic cell 6, a, has a juxtanuclear clump of the so-called hyaloplasm. Some authors would describe this as a Hof in the region of the centrosomum. Careful focusing, however, shows that the light areas of cells 5 and 6, a, are not homogeneous but contain many closely packed, yellowish or pale areas. Cell 6, b, is in prophase of mitosis and has a deeply stained, diffuse distribution of yellowish areas.

7, Bensley-Cowdry aniline acid fuchsin technique applied to dry smear. Most of the mitochondria are coccoid shaped but there are some short rods. Note their diffuse distribution.

8, Bensley-Cowdry aniline acid fuchsin technique applied to dry smear. Morphology of mitochondria is the same as in cell 7, but the distribution is quite different. There is a good correlation between perinuclear clear areas as shown in cell 5 and the perinuclear arrangement of mitochondria.

9, Bensley-Cowdry aniline acid fuchsin technique applied to dry smear. Morphology of mitochondria is the same as in cell 7, but the distribution is different from either of the preceding. There is a juxtanuclear clump of mitochondria, there are still some in the cytoplasm. Note the correlation between this type of mitochondrial juxtanuclear position of the clear area in cell 6.

10, Baker's formol-sudan black technique. The mitochondria appear as gray or grayish black coccoid and short plump rods. Some filamentous forms may also be seen, but they for the most part do not take on as much sudan black as the other forms. This cell has a diffuse arrangement of mitochondria.

11, Baker's formol-sudan black technique. The mitochondria appear as described for cell 10, but here they have a perinuclear distribution with some slightly out of focus superimposed on the nucleus.

12, Baker's formol-sudan black technique. Morphology of mitochondria is the same as in cell 10, but the distribution is that of a juxtanuclear clump. Faint filaments are present in the lower portion of the cytoplasm and they have varying degrees of curvature. The two black spheres to the left of the nucleus belong to the Golgi element.

X

Plate I
or legend, see opposite page.)

and 2, b, Plate 1, one wonders why so little use has been made of this technique in recent years. Studies of these preparations showed a good correlation between the distribution of mitochondria and the clear areas in the cytoplasm. In addition, the modified Schridde technique stained many more filamentous mitochondria than were ever seen with either dark-field illumination or the supravital technique. This very likely is due to the fact that the action of acid fuchsin is dependent upon the lipoidal nature of mitochondria,²⁶ hence this technique would bring out mitochondria with low refractive indices not seen with dark-field illumination and those without proteolytic enzymes not stained supravitaly. The advantage of this technique is that dry films may be stained specifically for mitochondria and compared with dry films stained with the standard hematologic dyes.

B. Embryonic Rat Blood Cells.—

1. *Dry Films of Blood From Yolk Sac of Eleven-Day Rat Embryo:* As indicated in the Introduction, these studies were transferred to primitive erythroblasts of the rat embryo because of the availability of material. This was advantageous because these cells are larger and have more cytoplasm. Careful examination revealed many bizarre arrangements of the so-called hyaloplasm. Cell 3 is of interest because of curved areas which, in one instance, appeared horseshoe-shaped. Areas which have a similar appearance have been described and illustrated by Sundberg and Downey²⁷ in reticular lymphocytes as representing cracks in the basophilic spongioplasm filled with clear hyaloplasm. This quite naturally implies an absence of definite structure, if we adhere to the accepted usage of the term hyaloplasm.²⁸ In all probability some of these light areas in other cells have been called trophospongium or canaliculi.²⁹ In a fair percentage of the cells examined, these areas in the cytoplasm had a very definite yellowish tinge. This perhaps would have been ignored, if it had not been recalled that Bensley³⁰ described extracted liver mitochondria as having a yellowish appearance. In spite of subsequent findings which indicated that a carotenoid pigment is present, it is still not known whether or not this coloration can be attributed to the stain or to the natural state of these cytoplasmic areas. Right or wrong, it fortified the evidence favoring the mitochondrial nature of the so-called hyaloplasmic areas and led to other investigations the results of which justified the original assumption.

Early in the course of these investigations it was thought that perhaps one way to solve this problem was to determine the incidences of various configurations of the so-called hyaloplasmic areas as seen in dry films stained with May-Grünwald-Giemsa and to correlate them with the incidences of known mitochondrial configurations. Primitive erythroblasts may be divided into three groups according to the distribution of the light areas. In the first group the cells have a more or less diffuse arrangement as illustrated by cell 4, Plate I. Such cells constitute about 60 per cent of all erythroblasts. In the second group the cells have a greater concentration of the light areas around the nucleus, forming a perinuclear Hof. In general, cytoplasm between this perinuclear clear area and the cell margin is more homogeneous than that in the first type. Compare cells 4 and 5, Plate I. The third group is made up of cells

having a fairly well-defined accumulation of clear areas more or less to one side of the nucleus, a juxtannuclear clump as shown in cell 6. In some instances this juxtannuclear light area would be separated from the nucleus by a band of basophilic cytoplasm and in others it would be in contact with the nuclear membrane. Careful examination of these juxtannuclear light areas, as well as perinuclear areas, revealed that they are composed of many closely packed yellowish or pale cocci-shaped and short plump rodlike areas. Cells of groups two and three constitute about 30 and 10 per cent, respectively, of all primitive erythroblasts. Additional illustrations of these cells may be found in articles dealing primarily with nuclear structure^{1, 31} and in a recent one concerning cell potentialities.³²

2. *Supravital Preparations of Blood From Yolk Sac of Eleven-Day Rat Embryo:* In general, the observations made on the chick cells stained with janus green or pinacyanol apply equally well for rat embryonic blood so that they need not be repeated here. However, it is important to describe the staining reaction of embryonic rat cells to neutral red. Granules or vacuoles (6 to 18) of variable size usually appeared in that region of the cell referred to as the centrosphere which in most instances also represented the area with the greatest concentration of mitochondria. All granules or vacuoles were not limited to this area because many were found around the nucleus, as described by Sugiyama⁵ for the chick. At the present time it is impossible to state whether or not all of the structures stainable with neutral red are identical in nature. However, there are some of these which enlarge greatly with time, while the others remain more or less the same size. Unfortunately Baker's¹⁵ method of using neutral red, which prevents an increase in their size, was not tried. Occasionally it was impossible to decide whether or not a few mitochondria were also stained with neutral red, especially in the case of the cocci-shaped mitochondria. Practically all of the neutral red vacuoles were colored uniformly, but in rare instances they had a chromophilic periphery and a chromophobic center. It has not been determined whether or not these would eventually develop into the first type. Cell 4 has a single clear round area in the upper left portion of the cell. This is not unlike some of the neutral red vacuoles with respect to size and position. Even though the cells in the supravital preparations were not flattened to the extent that they were in dry films, the distribution of the mitochondria corresponded to the distribution of the light areas previously described. In addition to this, there was ample evidence to indicate that some of the light areas, or so-called hyaloplasm, were due to structures which stained with neutral red in the living. In view of the recent articles by Baker¹⁵ and Worley,³³ the latter represent part of the Golgi element.

3. *Permanent Mitochondrial Preparations of Blood From Eleven-Day Rat Embryo:* All of the evidence thus far has indicated that the so-called hyaloplasmic areas, for the most part but not exclusively, represented negative images of mitochondria. The neutral red portion of the Golgi element contributed a very small part. If the centrioles contribute anything to the formation of these areas, it must indeed be very small, since they have not been demonstrated with certainty in any of the previous or subsequent studies. Quite

early in these investigations it was deemed necessary to correlate the distribution of mitochondria in dry films with that of the light areas demonstrable by routine hematologic stains. This quantitative approach to the problem was later abandoned in favor of a more direct one, namely, phase microscopy, which will be discussed in section B, 6.

Qualitative studies revealed that, in general, mitochondria of primitive erythroblasts had three types of distribution similar to the arrangement of the light areas described in sections A, 1 and B, 1. Compare cells 4, 5, and 6 with 7, 8, 9 of Plate I. For no reason other than that of convenience, Regaud's fixative was used more frequently than acetic osmic bichromate. In cells fixed with the former it was a fairly constant occurrence for the mitochondria to be thicker. This is in agreement with Baker's¹⁵ statement that potassium bichromate causes them to round up and swell. On the other hand, the acetic osmic bichromate seemed superior for the fixation of filamentous mitochondria. Cells 8 and 9 are of particular interest because in addition to the perinuclear and juxtannuclear distribution of mitochondria, quite a few are scattered throughout the cytoplasm. As a rule more mitochondria were stained with this technique than with the supravital technique. Although much criticism has been leveled against the use of dry films for cytologic studies, especially of the nucleus, it was interesting to note that mitochondria behaved as discrete structures resisting mechanical force. The evidence for this was that they were seen as fuchsinophilic bodies in the neighborhood of damaged or smashed cells. Lazarow³¹ has reported that free mitochondria from the guinea pig liver may at times retain their exact intracellular shape.

The correlation which has been described is nothing new in hematology. Forty years ago Schridde³⁵ maintained that the perinuclear clear Hof of lymphoblasts, as seen in sections stained with azure II-eosin or methyl green-pyronin, was nothing more than the negative image of accumulations of Altman-Schridde granules (mitochondria in present-day terminology). In a very critical review of this subject, Klein³⁶ discredited Schridde's view by stating that the mitochondria were not located in the perinuclear clear zone but more peripherad. He further maintained that the perinuclear zone was an artifact. This and other polemics of that period centering around the unitarian and dualistic theories for hematopoiesis apparently caused hematologists to forget Schridde's original observation. Although the present study does not involve lymphoblasts, it seems as though both Schridde and Klein were correct to a certain extent, if a distribution of mitochondria like that in primitive erythroblasts obtains in lymphoid cells.

4. *Formol Sudan Black Preparations of Blood From Yolk Sac of Eleven-Day Rat Embryo:* If all of the previous observations were correct, then it should be possible to apply certain histochemical techniques in order further to analyze the true nature of the so-called hyaloplasmic areas. It has been known for some time that mitochondria contain lipoid (in general sense). Bensley³⁰ reported that mitochondria from guinea pig liver contain about 35 per cent total lipoid and Goerner³⁷ found that they ranged from 27.0 to 32.4 per cent in the rabbit liver. It has been rather paradoxical to know that in spite of this

high lipid content, mitochondria did not stain with sudan III or IV.^{20, 28} This has been attributed to the lipid being inaccessible to sudan in a lipoprotein complex, and Bensley³⁰ has suggested that these negative results were due to the fact that the fat of the mitochondria was dispersed in ultramicroscopic form. In the past, one way to unmask these lipoids was to use the rather tedious procedure of Ciaccio outlined by Bowen,²⁹ but sudan black readily accomplishes this physically rather than chemically. Lison¹⁴ reported the superiority of sudan black over all other similar dyes for demonstrating total fat histochemically. This is due to the fact that sudan black has a great affinity for all lipoids and readily dissolves in them. Perhaps equally important is the fact that blue blacks and black are more discernible than the various oranges, reds, etc. Sudan black also has another important advantage which has been pointed out by Baker,¹⁵ namely, that it does not have a tendency to form connecting bridges between the structure in which it is deposited and another. It was my good fortune to have Mr. E. R. Hayes, who has been studying the histochemistry of the adrenal cortex, introduce the use of sudan black in our laboratory.

After having studied mitochondria by means of the supravital and Bensley-Cowdry techniques and dark-field illumination, it was not difficult to identify them in formol-sudan black preparations. For the most part they appeared as gray or grayish black cocci and short plump rods. Filamentous forms varied in their color from gray to a color which was almost indistinguishable from that of the surrounding cytoplasm. Since sudan black was available to all parts of the cell, it is justifiable to conclude that mitochondria within a given cell differ in their lipid composition. In general, the distribution of the mitochondria could be divided into three main categories, namely, diffuse, perinuclear, and juxtannuclear, as illustrated in cells 10, 11, and 12 of Plate I. In addition to the mitochondria, there were a few spherical sudanophilic structures which constantly appeared black or bluish black. Two such structures are illustrated to the left of the nucleus in cell 12. In most instances they appeared as sudanophilic throughout, but occasionally some with sudanophobic cores were encountered. They ranged from zero to eight per cell and were perhaps more constantly associated with the accumulation of mitochondria than any other region. In view of Baker's¹⁵ work, these structures are in all probability related to the Golgi element and will require further study. The present evidence suggests that a clear spherical area like that in cell 4, Plate I, represents the negative image of a portion of the Golgi element.

The sudan black preparations demonstrated that considerable sudanophilic material may be located above and below the nucleus as illustrated in cell 11. It is quite possible that this may explain the appearance of vacuole-like structures and rarefactions in some nuclei of leukemic cells.

From a cytochemical point of view, cells 11 and 12, Plate I, are interesting since the disposition of sudan black indicated that the perinuclear and juxtannuclear areas contain much more lipid than the surrounding cytoplasm. An attempt was made to localize protein in this area by the use of Millon's reagent.¹³ Thus far it has been impossible to demonstrate that protein is more concentrated in one part of the cell than it is in another. These observations

are contrary to those of Schleicher,³⁹ whose conclusions drawn from stained preparations alone have been too far-reaching. He has assumed that the Hof of pronormoblasts contains more protein than the perinuclear zone either because the fluid state of the Hof permitted protein to migrate there in the process of drying or because there is normally a greater concentration in that particular region. Although the present article deals primarily with a study of embryonic rat blood cells, sufficient material has been studied to indicate that in general the same conditions obtain for human bone marrow. In all probability some of the oxyphilic homogeneous patches in the cytoplasm which Schleicher described were the negative images of mitochondria.

Too much emphasis cannot be placed on the necessity of having good dry films for cytologic and diagnostic purposes. They should be rapidly dried and stained almost immediately for the best results. Most of us have obtained poor results after staining films which have been left overnight or longer. Quite recently some direct evidence was obtained which gave a clue to the possible nature of this process, which may rightfully be considered as degenerative. In order to study the stability of cytoplasmic structure in dry films, preparations were permitted to remain unfixed for four, six, and eight days, either in room air or in a desiccator. They were subsequently divided into three groups and stained by one of the following methods: May-Grünwald-Giemsa, Bensley-Cowdry, or formol-sudan black. There was certainly a loss of cytoplasmic detail as reported by Schleicher.³⁹ There was also a tendency for mitochondria to become less distinct. Fuchsinophilic and sudanophilic material appeared in portions of the cytoplasm not usually possessing these properties. The interpretation of sudan black preparations was that additional lipid material had been made available for the dye. Perhaps this was by the breaking down of lipoprotein complexes which Lison⁴⁰ discusses under the heading of lipophanerosis. There may also be some spreading of lipid material from the mitochondria to adjacent cytoplasmic areas. As to whether or not these processes are solely responsible for the alterations in the tinctorial qualities of cells stained with Romanowsky dyes, or a parallel phenomenon, cannot be stated at this time. In general, these changes were not as great in cells which were kept in the desiccator as they were in cells which have remained in room air.

Hematologists are beginning to find sudan black useful for studies other than those previously reported. Baillif and Kimbrough⁴¹ studied leukocyte granules in various stages of development in both normal and pathologic blood. Eosinophilic and neutrophilic granules exhibited a sudanophilia even when they were very immature. Basophil granules were entirely sudanophobic. In our laboratory, Kibler⁴² has found that Auer rods in acute leukemia are definitely sudanophilic, a property which distinguishes them from other forms of so-called azurophilic granulation including Kurloff bodies.

5. Reaction of Blood From Yolk Sac of Eleven-Day Rat Embryos to Antimony Trichloride: It already has been mentioned that quite early in these investigations the yellowish tint of the so-called hyaloplasm suggested a possible relationship of these areas to mitochondria. After this was established to a fair degree of certainly the most obvious thing to do was to deter-

mine whether or not primitive erythroblasts had carotenoid pigment localized within their mitochondria. Joyet-Lavergne⁴³ and Bourne³⁵ have applied the Carr-Price¹⁷ reagent of antimony trichloride in chloroform to a wide variety of plant and animal tissues. Due to the fact that vitamin A produces an intense blue reaction with this reagent and carotene produces a greenish blue color, these authors were unable to determine exactly which of these carotenoids was present or whether both were. Goerner,³⁷ however, using chemical methods which permitted a more exact analysis of isolated mitochondria, was able to show that they contain vitamin A. In the course of studying liver, cardiac muscle, and genital glands of birds, reptiles, amphibians, and fish, Joyet-Lavergne⁴⁴ observed that some red cells showed traces of vitamin A. Since its absence was not the general rule, he conducted further studies on the blood of the skate. Red blood cells of the skate were grouped into three categories depending upon their reaction to the Carr-Price reagent. Cells belonging to the first group, which were the most numerous, had fine blue filaments near the nucleus with rare granules and short rods in the rest of the cytoplasm. Those of group two were richer in fine blue filaments and granules than group one. The last group contained cells which failed to give a blue reaction. In order to localize this reaction, parallel studies of blood with mitochondrial techniques were conducted and showed a distribution of these elements similar to the three categories previously listed. According to Joyet-Lavergne, this confirmed the general proposition that vitamin A is an essential constituent of mitochondria. By the use of fluorescence microscopy, Popper⁴⁵ concluded that the appearance of some of the fine bars or droplets in epithelial cells simulated the appearance of mitochondria.

The results of the present study on primitive erythroblasts of the rat are of interest not only because they showed that these cells give a positive reaction to the Carr-Price reagent but because it was possible to localize this reaction within a single mitochondrion. For routine determinations of the presence of carotenoid pigment the best results were obtained by examining the preparations with a 4 mm. objective. As a rule the greenish blue color reaction appeared in ten seconds and lasted for twenty to seventy seconds before it commenced to spread throughout the cytoplasm and fade. The distribution of this color reaction corresponded in general to the three types of mitochondrial arrangement. By using a half aperture on the substage condenser diaphragm or oblique lighting it was possible to localize this reaction within a single mitochondrion with the oil immersion lens. Even long filaments reacted uniformly throughout. Careful examination of a mass of mitochondria similar to those shown in cells 6, 9, and 12 would often reveal many of the individual elements. Such an exact localization was made possible only by all of the previous studies leading up to this point. Although Andersen and Levine⁴⁶ have described a method for differentiating vitamin A from carotene, no attempt was made to do so in the present studies. Hence, the reaction obtained in the embryonic rat cells may indicate the presence of either one or both of these substances. However, the results of Goerner's³⁷ work suggest that we were very likely dealing with vitamin A.

One of the most surprising findings in these experiments was that cover slip preparations of embryonic blood kept in the dark gave a positive reaction to antimony trichloride as long as four months after they were made. There did not seem to be an appreciable loss in the intensity of the color reaction. Bodansky⁴⁷ has pointed out that vitamin A in nature is quite resistant to oxidation and attributed its stability to the presence of antioxidants. Popper⁴⁸ observed that tissue sections kept in plasma or serum did not lose their vitamin A as rapidly as those kept in water. This he believed was due to the presence of some protective principle. Such a thing may very well explain why dry films of embryonic blood retained their vitamin A after four months, since the cells were surrounded by a thin film of dried plasma. For a discussion of the significance of the presence of vitamin A in mitochondria see Bourne.²⁶ So far it has been impossible to determine the presence of vitamin C in primitive erythroblasts.

6. Correlation of Mitochondria With the Negative Images in the Cytoplasm by Means of Phase Microscopy: Up to this point, both in the case of results reported by Schridde³³ and those previously mentioned, it has been possible to conclude that the light areas in the cytoplasm of dry films stained with Romanowsky dyes represent, for the most part, negative images of mitochondria, only by making parallel studies with several techniques and correlating the findings. Although all of the accumulated evidence has pointed in this direction, technical difficulties have made it impossible, until quite recently, to say with certainty that small groups of mitochondria or even a single mitochondrion as seen in an unstained preparation will appear as a negative image when stained with routine hematologic stains. Phase microscopy¹⁴ has provided the answer to this problem.

Unstained dry films were usually mounted on a drop of Baker's formol-calcium fixative. The rationale for this was twofold. First, the mounting medium should be of such a nature that it would not only fix the cells to the cover slip but that it would also prevent the passage of lipoids into colloidal solution. Second, it should permit subsequent staining with either a routine hematologic stain or sudan black. The prime objective was to locate, by means of optical differentiation, filamentous mitochondria not necessarily associated with either perinuclear or juxtanuclear accumulations of these structures, and then determine whether or not they appeared in the stained preparations. By using this approach it was possible to decide definitely that the streaks, crevices, curved areas, and structures which suggest canaliculi in the basophilic cytoplasm are truly the negative images of mitochondria. For example, the horseshoe-shaped clear area of cell 3 represents the negative image of an underlying mitochondrion. Such a configuration is not an uncommon finding in primitive erythroblasts. However, it is important to realize that not all mitochondria will appear as negative in a dry fixed smear stained with one of the Romanowsky dyes. The extent to which they may be visualized is dependent upon how deeply they are located within the cytoplasm. As a rule the more superficial mitochondria located by bright contrast phase microscopy are the ones which will readily appear as negative images. The deeper ones which are even diffi-

cult to visualize with bright contrast are usually obscured by the overlying basophilic cytoplasm in routine preparations. If the mitochondria are grouped, as in perinuclear and juxtannuclear accumulations, then their representation as a negative image is practically assured in preparations subsequently stained with Wright's stain.

When unstained dry films are studied with bright-field microscopy considerable structure may be demonstrated in the cytoplasm, if the condenser diaphragm is closed about one half. As a matter of fact, cell 13, Plate II, contains more structure than Isaacs¹⁵ allows for stained cells which he calls megaloblasts. When these cells were studied with bright- and dark-contrast phase microscopy, details previously lost in diffraction patterns were made much more distinct. Cells 14 and 15, Plate II, show short rodlike mitochondria and ringlike structures. The latter will be described more fully later. Cells 16 to 18, Plate II, are of particular interest since most of the mitochondria were distributed in the same optical plane. Attention is directed to the morphology and relative position of the mitochondria in unstained cells 16 and 17. After the same cells were dried and stained with Wright's stain, most of the filamentous forms appeared as negative images in the deeply basophilic cytoplasm (cell 18, *a*, Plate II). In addition to these, the perinuclear accumulation of mitochondria and Golgi elements shown in cells 16 and 17 also appeared as negative image areas. These are undoubtedly identical with the light areas in the cytoplasm of proerythroblasts which Naegeli²² described and illustrated without knowing their true nature. A comparison of cells 16 and 17 with cells 18, *a* and 18, *b*, Plate II, should be very instructive to hematologists because of their size differences. Measurements of the mean cell and nuclear diameters shows that, after fixation and staining with Wright's stain, the nucleocytoplasmic ratios have been increased slightly. In the case of 18, *a* it changed from 60 to 67.4 per cent. This was due to the fact that alcoholic fixation caused a relatively greater shrinkage of the cytoplasm than that of the nucleus. In section B, 3 it was pointed out that mitochondria in damaged cells behaved as discrete structures resisting mechanical force. In cell 18, *a* the curved filamentous light area (mitochondrion) behaved in a similar fashion. Although its relative position with respect to the nuclear membrane and edge of the cell was altered, the morphology was undisturbed by shrinkage. In a subsequent article it will be shown that cells in dry films swell when placed in an aqueous medium and shrink with alcoholic fixation even after they have been flattened and dried. Cell 18, *b* is of interest because of the diffuse distribution of the light areas which correspond to the structures illustrated in cells 16 and 17, Plate II.

One of the most striking things revealed through phase microscopy was the high degree of organization present in the cytoplasm of primitive erythroblasts after they had been smeared and dried rapidly. A false impression is obtained if cells like those illustrated in 8, 9, 11, and 12, Plate I, are studied with one technique alone. The impression that mitochondria are more or less heaped about the nucleus was discredited through the use of phase microscopy which revealed that they have a more general distribution and that there are some forms which do not stain readily with either acid fuchsin or sudan black. This

very likely is due to the fact that the results of those techniques depend upon the fatty nature of mitochondria²⁶ which is variable, and the heat treatment may have caused some filaments to break up. In spite of all the structure revealed through phase microscopy, at no time was it possible to locate anything which even approximated what we designate as a "classical Golgi net or apparatus." Furthermore, it has also been impossible to locate in dividing cells a structure which could be called a centriole.

Much valuable information was obtained by combining the formal-sudan black technique with dark contrast phase microscopy. According to Lison⁴⁰ and Baker,¹⁵ whatever appears blue black consists of lipoids. Hence, mitochondria must vary in their lipid content because they appear as grayish structures and some, especially the filamentous forms, must contain a minimal amount. When such forms have been suspected of being located within a certain cytoplasmic area, the use of phase microscopy has made their presence a certainty. In section B, 4 it was mentioned that the sudanophilic solid spheres and those with a sudanophobic core were probably related to the Golgi element. With the aid of dark-contrast phase microscopy it was possible to determine that in addition to these forms there are sudanophilic rings which pass around sudanophobic cores in a manner quite similar to that described by Baker.¹⁵ They also resembled osmiophilic platelets of plant cells.⁴⁰ This finding tends to strengthen the view that the reason for not being able to locate a classical Golgi apparatus within primitive erythroblasts is probably not due to the fact that it was not preserved but rather that it does not exist as such. All of this will require further study.

7. *The Action of Ribonuclease on Basophilic Cytoplasm:* As a conclusion to all of the preceding sections which have dealt with the nature of the light areas in basophilic cytoplasm, it seems appropriate that the latter should also be analyzed in dry films. Basophilia of lymphocytes was identified by Brachet⁵⁰ as ribonucleoprotein by digesting sections of the spleen in a crude preparation of ribonuclease. Recently, Wislocki and Dempsey⁵¹ have shown that the basophilia of definitive erythroblasts in sections of monkey's bone marrow was abolished

PLATE II

Cells 13 to 17 were mounted in 10 per cent formalin and photographed at a magnification of 1610 diameters. Cells 18, a, and 18, b, were mounted in elarite and photographed at a magnification of 1625 diameters.

13, Unstained cell as seen with bright-field microscope at about half aperture. Although there is considerable cytoplasmic structure in this cell, the detail is lost in diffraction patterns.

14, Bright contrast with $0.21\lambda + 0.2\lambda$ diffraction plate. Note the rod and ring forms to the right of the nucleus. In sudan black preparations the rings appeared sudanophilic and are probably related to the Golgi element.

15, Dark contrast with $2.3B - 0.33\lambda$ diffraction plate. This was focused at a slightly lower level than cell 14 in order to demonstrate structures to the left of the nucleus which appear as dark rods. Ring forms previously described may also be seen to the right of the nucleus.

16, Unstained cells in bright contrast with $0.21\lambda + 0.2\lambda$ diffraction plate. Note the curved and straight filamentous mitochondria in the upper half of cell a. Ring forms near the nucleus are also present.

17, Same cells as 16 in dark contrast with $2.3B - 0.33\lambda$ diffraction plate. Note the shape and relative position of the mitochondria in the upper half of cell a.

18, Same cells as in 16 and 17 after drying and staining with Wright's stain. Bright-field microscopy. The filamentous mitochondria appear as negative images in the basophilic cytoplasm. Although there has been considerable shrinkage, the morphology of the light areas is practically identical with that of the mitochondria demonstrated by phase microscopy.

The phase photo-micrographs were furnished by M. D. Diedrich, Director of the American Optical Company, Scientific Division, Buffalo, N. Y., and the plates were arranged by M. D. Diedrich, Director of

after digesting them in a solution of crystalline ribonuclease. In our laboratory, cover slip preparations of dry films of embryonic blood have also been successfully treated with a similar solution of crystalline enzyme* and the basophilic material in the cytoplasm and nucleoli has been identified as ribonucleoprotein. These preparations were fixed briefly in Zenker-formol and controls were incubated in buffer solution. Either methyl green-pyronin or Wright's stain were used as counterstains. Cytoplasm of digested cells stains quite acidophilically with the latter. At the present it is impossible to state how much of this reaction may be attributed to hemoglobin which has been uncovered.

DISCUSSION

It is impossible in the space allotted to discuss adequately all of the ramifications of a problem which was started over seven years ago as merely an investigation of the pale or light cytoplasmic areas of primitive erythroblasts. It has grown and extended well beyond the limits of pure morphology due to the development and application of newer histochemical and optical techniques. All of the evidence presented indicates that it is no longer logical to ascribe a hyaloplasmic nature to the clear areas of cytoplasm in primitive erythroblasts since, contrary to being the clear and more fluid ground substance of protoplasm, they actually represent the negative images of definite formed bodies. The use of the term hyaloplasm has been varied. When Pappenheim²¹ adopted the term paraplasm (hyaloplasm) he did so not only because accurate descriptive terminology was lacking in the field of morphologic hematology, but also because most cytologists were still using this term in the sense originally employed by Leydig.⁵² To say the least, the two terms, spongioplasm and hyaloplasm, have served a useful purpose in the absence of more specific information regarding the true nature of these substances.^{1, 6, 25, 27} However, most cytologists have forsaken this interpretation of cytoplasmic structure in favor of one which considers the hyaloplasm to be the continuous phase of a polyphasic colloidal system. It is the clear, apparently homogeneous ground substance in which formed bodies are suspended.^{26, 28, 53, 54} When Pappenheim⁵⁵ published his work he continued to use the term paraplasm (hyaloplasm) in its original sense.⁵⁵ During this same period Schäfer⁵² deplored the fact that certain cytologists had introduced confusion into the terminology by employing the term hyaloplasm in a different sense. In spite of the fact that most hematologists have continued to use the terms spongioplasm and hyaloplasm (paraplasm) to describe the basophilic cytotritium and the lighter interspongioplasmic material present in lymphoid cells, biologists abandoned this usage long ago. In all probability the hematologist continued to use these terms because he had little or no interest in the actual structure of cytoplasm beyond what knowledge was necessary for the classification of cells.

Perhaps one of the most important findings in the present investigation is that since 1880 hematologists have been making dry film preparations which

*Crystalline ribonuclease was kindly furnished by Dr. E. A. Sharp, Department of Clinical Investigation, Parke, Davis & Company, Detroit, Mich.

preserve cytoplasmic detail with an extraordinary degree of accuracy. It seems to me that hematologists should not be castigated so much for using the dry film method of studying blood,³⁶ as for not having endeavored to find out the nature of some of the things which they have repeatedly described and perhaps argued about. To be sure, new techniques should be devised and used but not to the extent that the older ones are not developed and utilized to their optimum. Cunningham and Tompkins²³ pointed out that the methods of Ehrlich and Romanowsky are not capable of demonstrating certain specific data which the supravitral technique reveals. This is only partially true in the case of primitive erythroblasts from the chick and rat, for we now know that a fairly accurate estimate of the mitochondrial distribution may be obtained from a study of good dry smears alone. This reevaluation of what can be seen in dry films and its interpretation increases the usefulness of this method for studying the influence of antianemic substances transmitted across the placenta.^{7, 8} Cell size, nuclear structure, and the general mitochondrial distribution may all be studied in a single properly prepared dry film of embryonic blood.

The use of dry films of the embryonic yolk sac was introduced by Kirschbaum^{11, 31} primarily for the purpose of studying the nuclear structure of mammalian embryonic blood cells and comparing these with the megaloblasts of pernicious anemia. Later, this material was found suitable for studying the influence of antipernicious anemia principle on embryonic erythropoiesis.^{7, 8, 57, 58} The present article has revealed that this material is particularly suitable for investigating the cytochemistry of a single cell. Although the latter has been limited to only a few techniques, it is hoped that additional ones will be applicable to this material and that our knowledge will be extended in this new and interesting field. The method of approach outlined in the preceding pages may very well be applied to other cell types with slight modifications necessary to suit the individual problem.

At the present time it is impossible to predict what practical applications in clinical hematology will arise from knowledge that negative images of mitochondria are demonstrable with routine hematologic stains. Perhaps it may lead to a differentiation between macronormoblasts found in the marrows of patients with hepatic cirrhosis and those in the marrows from patients with various hemolytic anemias. It will be interesting to determine whether or not vitamin A is present in the former. Finally, megaloblasts must now be restudied in light of these recent findings.

SUMMARY

1. Blood from the yolk sacs of eleven-day rat embryos was studied by means of various cytologic, cytochemical, and optical techniques.
2. Freshly dried films of primitive erythroblasts preserve cytoplasmic detail to an extraordinary degree.
3. Light areas in basophilic cytoplasm previously described as hyaloplasm or paraplast represent, for the most part, the negative images of underlying mitochondria.

4. Cytochemical techniques reveal that the light areas (mitochondria) are relatively rich in lipid material and contain a carotenoid pigment, probably vitamin A. Cytoplasmic basophililia is due to ribonucleoprotein.

5. Phase microscopy makes it possible to study structures in unstained blood cells which are usually hidden in routine preparations.

INDUCTION OF LEUKEMIA IN EIGHT INBRED STOCKS OF MICE VARYING IN SUSCEPTIBILITY TO THE SPONTANEOUS DISEASE

ARTHUR KIRSCHBAUM, PH.D., M.D., AND HARRY W. MIXER, M.S., M.D.*
MINNEAPOLIS, MINN.

THE incidence of spontaneous leukemia in inbred mice is dependent on the genetic constitution of the strain. If a chemical or physical agent is to be considered "leukemogenic" then its administration must result in (1) an increase in the incidence of leukemia among test as compared with control mice of the same stock, (2) an accelerated onset of the disease, or (3) both effects.

Using these criteria, agents of three general types, two chemical and one physical, have been considered to be leukemogenic. The chemical agents are first carcinogenic hydrocarbons, such as carcinogenic tar,⁸ methyleholanthrene,^{11, 24, 27, 32} benzpyrene,^{24, 31} and 9, 10-dimethyl-1, 2-benzanthracene,^{17, 26} and second various estrogens.^{14, 15} Ionizing radiations such as x, gamma, and beta rays represent the physical agents capable of inducing this effect.^{7, 10, 17}

Included under the term "leukemia" in mice are systemic lymphatic and myelogenous leukemia and both localized and metastatic lymphosarcoma. Certain high leukemia stocks develop all these disease types spontaneously.²³ The induced disease has usually been lymphoid in our experience, except in those instances where the stock of mice develops myeloid leukemia spontaneously.²⁵ Morphologically and clinically these human and mouse diseases are very similar.⁹ Response to therapeutic agents is comparable in both species.^{5, 6, 12, 13}

Susceptibility to the induction of leukemia cannot always be correlated with susceptibility to spontaneous leukemia.^{8, 21, 33} Furthermore, x-rays may induce leukemia in stocks which are refractory to the chemical carcinogens.²¹ This report represents an analysis of these phenomena in eight inbred stocks of mice.

MATERIALS AND METHODS

Control groups for each stock of mice (except C57 Black) were observed by us. The strains used for experiments were dba-subline 212, Bagg albino, CBA, C3H, Strong A, NH, C57 Black, and F. In each stock (except C57 Black) the offspring of the controls were used as test animals. All mice were fed a diet of Purina fox chow and were permitted to breed to the extent that treatment with the leukemogenic agents allowed. A total of 1,400 mice were observed; the number used for each experiment is indicated on the bar graphs (Figs. 1 to 5) and tables.

Mice were placed on experiment at 10 weeks of age. Methyleholanthrene was administered by skin-painting, the carcinogen being dissolved in benzene as a 0.25 or 0.5 per cent solution. The solution was applied with a camel's hair brush ($\frac{1}{8}$ by $\frac{1}{8}$ inches), a different

This investigation has been aided by grants from The Jane Coffin Childs Memorial Fund for Medical Research, the National Cancer Institute, and the Cancer Fund of the Graduate School of the University of Minnesota.

*National Cancer Institute Trainee in Radiology.

area of the skin receiving the carcinogen with each painting. Animals were painted three times weekly with the weaker and twice weekly with the stronger solution. Estrogen was administered to Bagg albino and CBA mice in the form of a subcutaneous pellet of estrone* and to C3H animals by a single subcutaneous injection of 50 gamma weekly (throughout the experiment) of estradiol dipropionate in 0.1 c.c. of sesame oil. X-rays were administered by whole body irradiation, 140 kv., 30 cm. distance, 2 mm. aluminum filter. The mice were kept in a cardboard container while receiving radiation. Roentgens in air and interval of application are indicated on the bar graphs and their legends (Figs. 1 to 5) and in the tables (Tables I to VIII).

Leukemia was diagnosed by both gross and microscopic examination. The disease was detected in most of the animals ante mortem by physical examination.

RESULTS

Strain dba-Subline 212 (Table I and Fig. 1).—Following only eighteen paintings of a 0.25 per cent solution of methylcholanthrene in benzene, there was an increase in the total incidence of leukemia and an acceleration in the onset of the disease (Fig. 1, b). If the carcinogen was applied three times weekly and this treatment was continued until the animal was sacrificed because death seemed imminent, these effects were accentuated (Fig. 1, c). X-rays were also leukemogenic for this strain, but not to the same degree as methylcholanthrene (Fig. 1, d, e, and f). In spite of the fact that in this stock mammary cancer occurs spontaneously (Table I), and its onset was accelerated by the action of methylcholanthrene, and some females probably died as a result before leukemia developed, the incidence of leukemia was consistently higher in females (Table I). This suggests that female animals of this stock may be more sensitive than males to the development of both spontaneous and induced leukemia. Other investigators have noted that in certain stocks females develop leukemia more readily than males³ and the incidence may be reduced by ovariectomy,^{30, 34} although this phenomenon is not universal.²⁰

It may be concluded that strain dba-212 is moderately susceptible to the development of spontaneous leukemia. Upon administration of methylcholanthrene, or exposure to x-rays in appropriate doses, leukemia appeared earlier

in life than in untreated mice of this strain, and the incidence of the disease was increased. Susceptibility to the leukemogenic action of estrogenic hormone could not be determined because this stock does not tolerate the doses of estrogen known to be necessary for leukemogenesis in susceptible strains.

Strain CBA (Table II and Fig. 2).—Five out of seventy-six untreated CBA mice developed leukemia spontaneously (Fig. 2, *a*). When treated with methyleholanthrene none of thirty-four animals developed leukemia (Fig. 2, *b*).

Fig. 1.—Illustrates the incidence of leukemia in controls of the dba-212 strain and in mice of this stock which were treated with methylcholanthrene or exposed to x-rays.

Because of the development of skin cancer resulting from the action of methylcholanthrene (Table II), none of these mice survived beyond 350 days of age. However, if methylcholanthrene were leukemogenic for this strain leukemia should have appeared before this age (compare Figs. 1, *c* and 2, *b*). Although

CBA

*Indicates "dead, without leukemia"; animals received MC 0.50% plus 200 r of x-rays given on the day preceding the first skin painting.

**Indicates "dead, without leukemia"; animals received only 0.50% MC.

Fig. 2.—Illustrates the incidence of leukemia in control CBA mice and in animals of the same stock which were treated with methyleholanthrene, exposed to x-rays, or treated with

CBA mice were refractory to the leukemogenic action of methyleholanthrene, x-rays proved to be a potent leukemogen (Fig. 2, *c*). A single dose of 200 or 400 r is probably above the threshold range for this strain, although such doses were not as effective as much higher doses in inducing leukemia (compare Fig. 2, *c* and *g* with *c*). Estrone induced leukemia in two out of seventeen mice (compare Fig. 2, *a* and *d*). In contrast to the dba strain leukemia was not induced more readily in female than in male animals (Table II). The development of mammary cancer was not a complicating factor in this stock.

Estrone pellet	16	16	0	7	7	0	0

*Methylcholanthrene.

Strain Balb (Table III and Fig. 3).—Although a large number of the seventy-seven control animals are still alive, those living have reached sufficient age (Fig. 3, *a*) to serve as controls for the induction of leukemia in this stock. Only one case of leukemia has appeared among the controls. When treated with methyleholanthrene, although a large per cent of the mice developed skin cancer (Table III), these animals were of such an age (Fig. 3, *b*) that cases would have appeared in this group if methyleholanthrene were leukemogenic for this stock. When 200 r of x-rays were given monthly for nine successive months, ten out of sixteen animals developed the disease (nine of eleven females and one of five males). Estrone was almost as potent a leukemogen as x-rays from the standpoint of the total number of leukemias induced and was more active from the standpoint of latent period (compare Fig. 3, *c* and *d*). Only male mice were tested with estrone pellets, since females of this stock develop pyometra and all die within 200 days after implantation of the pellet.

Thus, Bagg albino mice were relatively refractory to the development of spontaneous leukemia, and proved to be absolutely refractory to the leukemogenic action of methyleholanthrene, but susceptible to x-rays or estrone as leukemia inductors.

Fig. 3.—Illustrates the incidence of leukemia in untreated Balb albino mice and in groups treated with methylcholanthrene, x-rays, or estradiol dipropionate.

Fig. 4.—Illustrates the incidence of leukemia in control C3H mice and in mice of the same stock which were treated with methylcholanthrene, x-rays, or estradiol dipropionate.

†Thirty out of thirty-nine mice with the mammary cancer "milk-agent" developed mammary cancer.

‡Twenty-three of the thirty-one females in this group lacked the mammary cancer "milk-agent."

§Methyleholanthrene.

*Strain C3H** (Table IV and Fig. 4).—No leukemias were observed in eighty-two control mice, nor was leukemia induced in any of thirty-one animals painted with a 0.25 per cent solution of methyleholanthrene in benzene. In a group of 29 C3H mice which received a total of 880 r of x-rays (80 r on eleven successive days), two animals developed leukemia. The same number of leukemias appeared in a group of twenty-eight animals which received 50 gamma weekly of estradiol dipropionate. In all groups a considerable number of females developed mammary cancer (Table IV). As a result of painting with methyleholanthrene skin cancer was a cause of death so that very few mice treated with the carcinogen survived beyond 300 days of age.

The C3H stock of mice is thus a low-leukemia strain which was refractory to the leukemogenic action of methyleholanthrene, but probably somewhat susceptible to the leukemia-inducing action of x-rays and estradiol dipropionate. X-rays¹⁷ and estrogens¹⁴ have been demonstrated by other investigators to induce leukemia in C3H mice. In a previous experiment²⁵ C3H animals were refractory to methyleholanthrene.

Strong A Strain (Table V and Fig. 5, a and b).—In the present experiments x-rays were the only leukemogenic agent studied. Six cases of leukemia (Fig. 5, b) appeared among fifty-eight mice which received radiation with x-rays, whereas there were no cases in the group of ninety-two controls. Thus, although leukemia did not appear in untreated mice of the Strong A strain, these mice were moderately susceptible to the leukemogenic action of x-rays. In previous studies methyleholanthrene did not induce leukemia in this stock²¹ and estrogens were probably only very weakly leukemogenic.¹⁴

Strain NH (Table VI and Fig. 5, *c* and *d*).—Four cases of leukemia appeared in the group of 104 controls and seven cases in thirty-one animals receiving x-rays. This stock did not tolerate estrogens well and methylcholanthrene was not tested.

Strain C57 Black (Table VII and Fig. 5, *c* and *f*).—These mice were refractory to induction of leukemia by methylcholanthrene, but developed leukemia following radiation with x-rays (fifteen out of sixty-two mice). Methylcholanthrene-treated mice lived to be from 300 to 400 days of age; by 400 days of age, nine of the fifteen cases of leukemia induced by x-rays had appeared. This is a low-leukemia stock which was refractory to estrogenic hormone as a leukemia incitor.¹⁴ Susceptibility to the leukemogenic action of x-rays has been reported previously in this stock.¹⁶

Strain F (Table VIII and Fig. 5, *g* and *h*).—This is a high leukemia stock (Fig. 5, *g*) in which leukemia appeared precociously when the mice were skin painted with methylcholanthrene.^{24, 25} This strain did not tolerate x-rays well in the doses given (in Fig. 5, *h* note deaths without leukemia at an early age). The relatively poor general status of these animals following radiation might account for the fact that x-rays failed to increase the incidence of leukemia during the first year of life (Fig. 5, *g* and *h*). The doses of x-rays used did not appreciably decrease the expected incidence of leukemia for this strain. Strain F mice do not tolerate estrogens in leukemogenic doses.

DISCUSSION

Evidently multiple agents (carcinogens, x-rays, estrogens) are capable of inducing leukemia in mice. The effectiveness of each agent depends on the

genetic constitution of the stock involved (Table IX). Although the actual mechanism of induction might be the same for each agent, specific genes probably determine whether the strain will respond to the particular stimulus. It would appear that leukemia may represent one type of neoplastic response to any one of several inciting agents.

X-rays represent the only agent which might be considered to be almost universally leukemogenic for mice. However, the degree of responsiveness to this agent varies from strain to strain. Estrogens are probably second in general effectiveness, and the carcinogenic hydrocarbons third, although when leukemogenic the last-mentioned represent the most potent leukemogen. Susceptibility to spontaneous and carcinogen-induced leukemia can be correlated (Table IX). However, some strains with a very low incidence of spontaneous leukemia developed a high incidence following treatment with carcinogenic chemicals.^{8, 33} Benzol has been reported to induce leukemia in mice, but the experiments were not conducted under controlled conditions using inbred stocks.^{28, 29} When dba mice were skin painted with benzene alone the incidence of leukemia did not differ from that found in controls.³²

		- ?		

±, 3 to 10% leukemia.

±, 10 to 15% leukemia.

++, 15 to 35 % leukemia.

+++ 35 to 50% leukemia.

++++, More than 50% leukemia.

All three proved leukemogens also induce cancer in mice. The carcinogenic hydrocarbons, of course, induce neoplasms of many types (skin cancer, sarcomas, lung tumors). X-rays induced ovarian tumors readily¹⁰ and among irradiated mice there was an increase in the incidence of miscellaneous tumors.^{10, 32} The estrogens have been demonstrated to induce cancer of the uterine cervix¹ and testicular tumors of mice.¹⁶ None of the other steroid hormones has been proved to be carcinogenic.

The fact that carcinogens are also leukemogens lends support to the idea that leukemia is a neoplastic disease. Transplantation studies indicate that mouse leukemia behaves in general as do the other neoplasms of this species.^{13, 23}

In these experiments treatment with leukemia-inciting agents was begun when mice were 10 weeks of age. Susceptibility to at least two of these agents (carcinogenic hydrocarbons and x-rays) was greater if administration was

begun earlier in life.^{10, 31} It is likely that the incidence of induced disease would be higher in most stocks if experiments were begun with younger mice. It is also possible that if younger animals were used certain stocks would prove not to be completely refractory to any agent. Under the conditions of these experiments, however, it is possible to make the comparison of leukemogenic effectiveness set forth in Table IX.

EVALUATION OF BONE MARROW CONCENTRATION TECHNIQUES

A MODIFIED METHOD FOR THE SIMULTANEOUS PREPARATION AND STAINING OF BLOOD AND BONE MARROW FILMS

LOUIS R. LIMARZI, M.D.*

CHICAGO, ILL.

CORRELATION studies of the peripheral blood and bone marrow in diseases of the hemopoietic organs is a firmly established and universally recognized procedure. Sternal marrow aspiration allows the investigator to study the blood cells in their formative stage. This knowledge has given him a new perspective into the diagnosis and management of blood dyscrasias. Sternal aspiration is not the sole method or answer to hematologic diagnosis but it is important in the proper evaluation of abnormal blood findings. In many cases it is the key to the diagnosis. The study of an abnormal blood picture is not complete without an analysis of the sternal marrow.

The two methods of sternal marrow biopsy in general use are the trephine and aspiration. Of these two methods sternal aspiration has many advantages; thus, it is the method of choice of most investigators. The one objection to this method is that along with aspiration of bone marrow cells one must of necessity withdraw peripheral blood (sinusoidal) at the same time. This may dilute the bone marrow so greatly that when one uses fixed films he may see only a few bone marrow cells on the film. This one objection has been overcome by the use of the concentration technique.

REVIEW OF THE METHODS USED FOR CONCENTRATING BONE MARROW CELLS

Several investigators have described methods for concentrating bone marrow cells. Reich¹⁶ in 1935, by means of a specially constructed needle which must be driven into the sternum, aspirated 10 c.c. of bloody fluid. This material was mixed with 2 c.c. of 1.4 per cent sodium oxalate solution and centrifuged, and films were made of the buffy layer. Recently, Reich¹⁷ has modified his original method by aspirating 4 c.c. of marrow fluid and concentrating the buffy layer a second time in a small tube. In 1937 Vogel and associates,²¹ in some of their bone marrow studies, aspirated 2 c.c. of marrow fluid and after using one drop of 30 per cent sodium oxalate as an anticoagulant, placed some of the marrow material in a Wintrobe tube and centrifuged it for five to ten minutes. In this way a relatively accurate red cell, white cell, and platelet volume was determined. Occasionally a fat layer was seen at the top of the tube. The white cell layer was carefully removed with a Wright capillary pipette and mixed to insure uniformity, and films were made. The disad-

Aided by a grant from Armour and Company.

vantages of the methods used by Reich and Vogel and associates are, first, that the large amount of marrow blood aspirated does not lend itself to accurate quantitative study in the hematocrit tube and, second, that the distortion of cell morphology, especially that of the nucleus, due to oxalates may be misleading. This may account for the number of unclassified cells recorded by some workers. Schleicher and Sharp¹⁸ in 1937 described a method of preparing and staining bone marrow in which heparin was used as an anticoagulant. Approximately 0.5 c.c. of marrow fluid was aspirated through a specially devised sternal needle (Klima and Rosegger type⁹) and placed into a small paraffin-lined test tube containing a sufficient amount of heparin to prevent coagulation. The heparinized marrow fluid was pipetted into a Wintrobe hematocrit tube and centrifuged at high speed for five minutes. The white myeloid layer in the hematocrit tube, plus an equal column of red cells (peripheral blood), was mixed with a volume of plasma equal to both of the cellular layers. The mixture of bone marrow cells, red blood cells, and plasma was mixed in a paraffin-lined watch glass, and margin-free films were made with a cover slip. The films were stained with May-Grünwald-Giemsa combination. The disadvantages of this method are, first, that the small amount of marrow fluid aspirated (0.5 c.c.) does not lend itself to accurate quantitative studies in the Wintrobe hematocrit tube and, second, that the dilution of bone marrow cells by the addition of the column of red blood cells (peripheral blood) defeats the purpose of concentrating marrow blood. In the method of Schleicher and Sharp the dilution factor is directly related to the quantity of the white myeloid layer; that is, the higher the column of bone marrow cells the greater the dilution with peripheral blood (column of red cells). A. S. Gordon⁴ in 1939 used post-mortem bone marrow material for the quantitative estimation of the cellular elements of the bone marrow and for differential studies. H. Gordon⁵ in 1941 described a method for preparing films and sections of the marrow fluid in which dry oxalate was used to prevent clotting of the marrow fluid. Accurate cytologic identification is difficult in post-mortem material, and the changes become more pronounced the longer after death one waits to study the bone marrow cells. The effect of oxalates on cytology of bone marrow cells has been discussed elsewhere.¹⁰

AUTHOR'S METHOD OF OBTAINING AND CONCENTRATING BONE MARROW CELLS

The method of sternal aspiration and preparation of marrow specimens with a detailed description of the apparatus (Fig. 1) and procedure was first reported by the author¹⁰ in 1939. To state it briefly: Under aseptic technique and procaine anesthesia the sternum (midline) is punctured in the second or third interspace, preferably the former site, with a specially devised 16 gauge needle.* This needle is one devised by Klima and Rosegger modified by Poncher and the author in 1937 for a Luer syringe attachment; thus, an adapter, as required for the original needle, is not necessary. The needle is forced into the bone perpendicular to the sternum until a sudden "give" indicates that the marrow cavity has been reached (Fig. 2). The stylet is then removed. With a tight fitting, dry 5 or 10 c.c.

*University of Illinois Sternal Needle, made by V. Muller and Company, Chicago, Ill. Although a guard is a part of the needle, from a practical point of view it is of little help in gauging the thickness of the anterior plate of the sternum. The guard serves its greatest usefulness by allowing one to obtain a firm grip of the needle while forcing it into the sternum. In obese individuals it may be necessary to remove the guard from the needle before attempting to enter the sternum.

FIG. 1.—Apparatus for sternal puncture (concentration technique) showing the Kilma and Rosegger sternal needle modified for Luer syringe attachment, paraffin-lined tube containing powdered heparin, Wintrobe hematocrit tube, paraffin-lined pipette, and watch glass.

2.—Sternal needle in position in the sternum at the second costal interspace. Note that the sternal needle in situ should be perpendicular to the sternum.

syringe, exactly 1 c.c. of marrow fluid is aspirated and immediately placed in a paraffin-lined tube containing a minute amount of heparin.* The tube is gently inverted several times to insure the anticoagulant effect of the heparin. Usually, if a successful sample of bone marrow has been obtained, a more or less dense suspension of small tissue particles will be visible.¹⁰ The 1 c.c. of heparinized material consisting of peripheral blood (sinusoidal), hemopoietic marrow, and fat is pipetted into a Wintrobe hematocrit tube and centrifuged for approximately five minutes at about 2,000 r.p.m. Centrifugation separates the following layers reading from top down in the tube (Fig. 3, A): (1) fat, yellow and

Fig. 3.—A, Hematocrit tube illustrating the composition of the several layers (volumetric) of the bone marrow material after centrifugation. B, Diagrammatic representation of the conventional bone marrow spread. The margin-free bone marrow film spread is made with an 18 by 22 mm. rectangular cover glass (same thickness as the counting chamber cover glass). red, (2) plasma, (3) myeloid-erythroid cells; this layer also contains the megakaryocytes, and (4) erythrocytes from bone marrow sinuses. The heights of the several layers are recorded.[†] The fat and most of the plasma are removed separately and discarded. The myeloid-erythroid layer, together with a small amount of plasma, is pipetted off separately, transferred to a paraffin-lined watch glass, mixed, and from this material, films and cell counts are made. This method has been followed by the author and his associates in more than 3,385 practically simultaneous studies of the bone marrow and peripheral blood.¹¹⁻¹⁴

*Powdered Heparin, Lot No. 153, Hyson, Westcott, and Dunning, Baltimore, Md. This type of heparin is inexpensive and 1.0 Gm. will suffice for approximately 350 to 400 sternal punctures.

†Normal average quantitative values for adults as represented in the hematocrit tube are as follows: Fat (yellow and red), 3.2 per cent; plasma, 45 per cent; myeloid-erythroid (M-E), 6.8 per cent; and erythrocytes, 45 per cent. Before any definite figures can be accepted, a large number of cases from all age groups are needed where quantitative studies are made from marrow obtained under standardized techniques. Of these values the myeloid-erythroid is of hematologic significance.

In the original method a small drop of marrow fluid is transferred to a new and perfectly clean microslide and with an 18 by 22 mm. rectangular cover glass a margin-free film is made (Fig. 3, B). The film is stained with Wright's stain or May-Grünwald-Giemsa dyes, except that a double concentration of Giemsa stain as recommended by Ferrata³ and Downey² is used. A control film that has been made from a drop of nonheparinized marrow fluid is also prepared in the same way.

Fig. 4.—The technique of making blood and bone marrow films on one microslide. A to D show the technique of making the blood film. The same technique is followed for making the bone marrow film except that the opposite edge of the microslide is used.

Preparation of Marrow-Blood Films by Double Slide Technique.—In order to utilize a microslide for films of both blood and bone marrow, the following technique is used: Place a small drop of concentrated marrow fluid on the near lower edge of a scrupulously clean standard 3 by 1 inches microslide approximately one-quarter of an inch from one end of the slide. With a second slide, one end of which is used as a spreader and held at an angle of 30 to 45 degrees (Fig. 4), touch the second slide to the first slide so that the drop of blood is within the angle thus formed. Draw the second slide toward the drop of blood until the end of the slide just touches the drop and the blood spreads along the acute angle by capillarity. A moment is allowed for this to occur, after which both slides are opposed and the blood "sandwiched" and spread between them. The slides are then immediately and quickly drawn apart. The first slide which contains the usable film of the bone marrow

is finally dried by air in motion.* On the opposite end of the same slide place a drop of blood from the finger or ear and repeat the procedure as described for making the bone marrow film. This bone marrow-blood microslide preparation is now ready for staining. Before staining, a thick line by means of a marking pencil is drawn along the inner edge of both the bone marrow and blood films (Fig. 3, C).† The marking pencil line serves to prevent the stain from overflowing and prematurely staining the blood film on the opposite end of the slide. Note that the bone marrow and blood films are spread along the width of the microslide rather than the conventional length of the slide. A good bone marrow

Fig. 5—Photomicrograph of the (A) peripheral blood and (B) bone marrow (megaloblastic erythropoiesis) from a patient with pernicious anemia made from a peripheral blood and bone marrow preparation as illustrated in Fig. 3, C.

*This method was first used by Dr. Raphael Isaacs for the preparation of either blood or bone marrow films.

†When May-Grünwald-Giemsa dyes or Wright-Giemsa stains are used for staining the bone marrow-blood preparation, one can dispense with the marking pencil line. Also, when the marking pencil line that separates the blood and bone marrow films can be dispensed with and the entire preparation as follows: Allow the Wright's stain to act for three minutes; then dilute with distilled water as the slide will hold, mixing very thoroughly. Allow this to stand for three minutes, and then wash with distilled water and air-dry. Properly followed, this will usually take care of the overstaining of the blood.

and peripheral blood preparation should be smooth, homogeneous, and have even edges. The films of the bone marrow and peripheral blood should occupy approximately the opposite one-third of the end of the slide, as seen in Fig. 3, C. The area between the inner edges of the bone marrow and blood films, after the preparation has been stained and the marking pencil marks have been wiped away, is sufficient space for ordinary labeling.

Staining of Bone Marrow and Peripheral Blood Preparation.—For general routine work, Wright's stain is most satisfactory.* The preparation is placed on a staining rack and the bone marrow film is stained first. The "square" with the bone marrow film is covered with Wright's stain and allowed to act for three minutes, this procedure serving to fix the smear. The stain is then diluted with distilled water,† as much as the lower end of the slide containing the marrow film will hold, mixing very thoroughly; the marking pencil line along the inner edge of the film prevents the stain from overflowing to the opposite side of the slide and staining the blood film prematurely. Allow this to stand approximately fifteen minutes; without washing immediately begin staining that portion of the slide with the peripheral blood film in the usual way that is, Wright's stain one and one-half minutes followed by distilled water for three minutes, mixing thoroughly. At this point the entire slide may become diluted following the overflow from both ends of the slide. The entire staining period should not exceed twenty minutes. Finally, rinse the entire slide with distilled water until the water runs, returning clean while tilting the slide. Wipe off the marking pencil marks and rinse with distilled water for a second time, place in a vertical position in a slide rack, and allow to air-dry. If this procedure is followed there will be obtained well-tinted bone marrow and peripheral blood preparations with no film or precipitated stain visible (Fig. 5).

Preparations made according to concentration technique give bone marrow patterns comparable in certain respects to those seen in bone marrow sections; thus, they are called "tissue-like" preparations. With the oil immersion objective, a differential count may be performed. This is simplified by the use of an ocular which contains a Whipple grid‡ to divide the field into segments. By moving the stage one can readily examine the peripheral blood; thus, the peripheral blood and bone marrow films are available for examination on the same microslide.

COMMENTS

The author's method of concentrating and preparing bone marrow has a number of advantages: (1) Myeloid-erythroid (M-E) hypoplasia and hyperplasia is relatively accurately measured; thus, quantitative changes (myeloid-erythroid volume in the hematocrit tube) as well as qualitative studies (differential counts of the bone marrow film) may be correlated. (2) The separation of the erythrocytes in the hematocrit tube, most of which are derived from the sinuses of the bone marrow, eliminates the admixture of peripheral blood that is responsible for the dilution of the bone marrow elements. (3) Fat which interferes with the proper staining of the bone marrow cells is removed by the centrifugation of the marrow fluid. It also gives a relatively accurate estima-

*Wright's stain is prepared by placing 100 c.c. of certified Wright powder on the surface of 600 c.c. of chemically pure methyl alcohol in a ball mill containing one charge of pebbles. The ball mill is rotated in an electrically propelled machine overnight. The stain is stored in a 800 c.c. dark brown bottle and allowed to stand about seven days. The stain is then poured into a 60 c.c. dispensing bottle and kept tightly corked when not in use. If a ball mill is not available, grind 0.1 Gm. of Wright powder with a few cubic centimeters of the alcohol in a mortar. Slowly add the alcohol, a few cubic centimeters at a time, until 60 c.c. of alcohol is added; then grind thoroughly. This process should stand one to two days. Filter before use.

†We have found from experience that double or triple distilled water gives better and more constant results than does a buffer solution of pH 6.4. Much of the cause of poor staining is due to the use of unclean slides or to poorly prepared films. A five gallon bottle of distilled water with an attached siphon is used for diluting Wright's stain and washing off the stain. The use of this water for as long as three months gives uniformly well-stained and well-tinted films.

tion of the amount of fat in the bone marrow specimen and is of value in the study of certain diseases. (4) The method lends itself to the preparation of a large collection of uniformly prepared and stained films for teaching classes in clinical pathology and hematology. The preparation of the blood film on the same microslide containing the marrow film is a practical method for the simultaneous study of hematologic material. It is an ideal method of filing both blood and bone marrow films for future reference.

One of the routine methods followed at the United States Naval Medical School¹⁵ for preparing the aspirated marrow blood is to concentrate bone marrow using an ammonium-potassium oxalate mixture* as an anticoagulant. Although this oxalate mixture causes little if any distortion of cell morphology, a control marrow film should be prepared from a drop of the marrow fluid before it is added to the anticoagulant.

A number of investigators, including Jones,⁵ Hebbel,⁶ Holly,⁷ Stasney and Pizzolato,²⁰ and Schleicher,¹⁹ have used the author's concentration technique for the quantitative and qualitative studies of the bone marrow in normal and pathologic conditions.

The histologic study of the bone marrow can be provided by the use of marrow particles either prior to or following heparinization and concentration of the marrow fluid. These are placed in Zenker-Formalin solution and the sections after fixation are prepared in the usual way with paraffin and stained with hematoxylin-eosin or Giemsa. Recently, Berman and Axelrod¹ have described a method of utilizing bone marrow aspiration material for volumetric readings, smears, imprints, and histopathologic sections. The sections are utilized in studying the topographic relationship of the bone marrow. Frequently these hemopoietic particles are too small to be of value. This is especially true in hypoplastic bone marrows. Then again detailed and accurate cell morphology and identification is not well preserved in sectioned material. Marrow blood that has been allowed to clot and treated as described for making histologic preparations is of little value for the study of bone marrow. Also, anyone whose experience with sternal aspiration has been at all intensive has observed cases in which it has been impossible to obtain bone marrow material for study, the so-called dry tap. This is observed in cases of myelosclerosis and myelofibrosis. Under such circumstances it is more appropriate to use a small trephine and remove a small plug of bone marrow. The bone marrow plug can also be used for making smears and imprint (abklatsch) preparations of the bone marrow.

Clinical hematology may derive a great deal of benefit from the study of the peripheral blood and bone marrow. However, it cannot be too strongly emphasized that data obtained by a study of all hematologic aspects of a case should never be sufficient to make a diagnosis. The clinical picture obtained by a complete history and thorough physical examination still remains the most important factor in all hematologic procedures and investigations.

*Ammonium-potassium oxalate mixture is prepared as follows: 1.2 Gm. of ammonium oxalate and 0.8 Gm. of potassium oxalate are dissolved in 100 c.c. of distilled water. Place 0.1 c.c. of this mixture in a small test tube and evaporate to dryness. This amount of anticoagulant suffices to prevent the clotting of about 1 c.c. of aspirated bone marrow fluid.

CONCLUSIONS

1. The advantages and disadvantages of bone marrow concentration techniques in general use for the preparation and studying of bone marrow are discussed.
2. A method is described which utilizes a microslide for the uniform preparation and staining of both peripheral blood and bone marrow films.
3. The advantages of the author's concentration technique for the study of bone marrow are discussed.

QUANTITATIVE CYTOLOGIC STUDY OF MULTIPLE STERNAL MARROW SAMPLES TAKEN SIMULTANEOUSLY

PHILIP PIZZOLATO, M.D.,* NEW ORLEANS, LA., AND

JOSEPH STASNEY, M.D.,† PHILADELPHIA, PA.

PREVIOUS qualitative and quantitative studies of the cytologic constituents of the bone marrow taken from widely separated portions of the marrow lead to the conclusion that there probably is a relative identity in the cellular organization of the red marrow throughout the body. Our former study was based on preparations obtained from fourteen persons after their accidental death.¹ The samples were obtained from three different regions shortly after death, and imprint preparations were made. In experimental work marrow samples were obtained from different portions of the marrow soon after the animal had been sacrificed.²⁻⁶ With this technique we found that cytologic appraisal of any region of marrow will reveal, within the limits of error, what is the trend of the marrow changes elsewhere in the body.

Recently, several authors⁷⁻⁹ found differences in the cellular composition of the different portions of the marrow, claiming that the marrow is not a homogenous structure. Reich and Kolb¹⁰ reported a quantitative study on a series of multiple sternal marrow samples, taken simultaneously, and concluded that quantitative determinations are inaccurate.

To ascertain the basically important point whether one marrow sample would give a representative picture of the bone marrow function in the present study, we examined quantitatively and qualitatively two portions of the sternal marrow by obtaining samples from two different sites simultaneously.

MATERIALS AND METHODS

Thirty patients with a wide variety of pathologic conditions at the Charity Hospital of Louisiana were used in this study. The marrow was aspirated through an 18 gauge spinal needle from two sites of the body of the sternum, about 2 or 3 cm. apart. Care was used to remove not more than 1 c.c. of liquid. The marrow upon removal was gently expressed through the needle into a bottle containing 2 mg. of ammonium potassium oxalate. From the material remaining in the needle, cover-slip preparations were made and rapidly dried by waving through the air; these were stained with Wright-Giemsa stain after several hours of additional drying.

From the oxalated marrow the total nucleated elements were counted employing white cell pipettes and diluting with 5 per cent acetic acid. The counts were done on the regular Levy counting chamber using 5 to 25 squares of the large central square, depending on the number of cells present. The following formula was used:

$$\text{Total nucleated elements} = \frac{\text{Number of cells counted} \times \text{dilution}}{\text{Volume of chamber}}$$

The unused marrow was placed in a Wintrobe tube and centrifugalized at 2,000 r.p.m. for five minutes and the percentage of the marrow fractions was tabulated according to the method of Limarzi.¹¹ With this technique, 5 to 8 per cent were found as normal values for

*After four days of liver treatment.

†After two weeks of liver treatment.

‡After one month of liver treatment.

bone marrow cells. We found the following distribution of the different fractions in the centrifugalized marrow in fourteen apparently healthy medical students, ten men and four women: fat, 1 to 3 per cent; plasma, 40 to 54; marrow, 3 to 11; and hematocrit, 40 to 51. The total number of nucleated elements was 43,000 to 105,000 per cubic millimeter. In the differential counts, a minimum of 500 cells was counted from each marrow sample. The damaged cells were counted also when encountered associated with well-preserved cells. The percentage distribution of all cells observed and the myeloid-erythroid ratio of each sample were computed and tabulated.

COMMENT

The numerical data are tabulated in Tables I to III.

In Table I, data for anemias and conditions leading to anemia are tabulated. Cases 1, 5, and 10 exhibit marked proliferation of erythroid cells with inversion of the myeloid-erythroid ratio. The values of these ratios in the two samples obtained from two sites of the sternum reveal differences but express a similar trend of changes.

Illustrated in Table II are cases of leukemic conditions with strikingly similar proliferation of the pathologic cells in the two samples. The case of idiopathic purpura in both samples shows relatively normal values.

In Table III are included, among others, cases with tendencies to form localized, nodular changes in the red marrow, like multiple myeloma and Boeck's sarcoidosis. The values for the myeloid-erythroid ratio, not including the pathologically proliferating cells, again reveal parallel changes in the two samples.

All the cases included were of different sex, age, and race with wide variety of pathologic conditions. Because of these great differences between the examined cases, no statistical analysis was attempted. A comparison between the cellularity of the two samples from the same sternum disclosed variations which reflected in the quantity of the different fraction of the marrow as well as in the total number of nucleated elements and in the percentage distribution of different cells.

The differences in the quantitative data may be caused by the technique of obtaining the samples. Dameshek and associates¹² pointed out that the tech-

nique used for obtaining marrow samples was itself a possible source for differences in quantitative values of different cells. They compared the results of marrow samples obtained through biopsies and by punctures. In the latter, the more immature cells and the fixed cells were less numerous than in samples obtained through biopsies. It is possible that the suction force applied at puncture draws back more readily the free cells than the more immature cells, which according to Isaac's conception¹³ are probably surrounded by firmer gelatinous substance than the mature cells. These marrow cells were enmeshed by a fine network of the fixed reticulum cells.

Another possible cause for the numerical differences is the unavoidable admixture with red blood cells. The larger the amount withdrawn, the more likely it is that the walls of sinusoids will rupture with resultant admixture with blood. Occasionally, even after withdrawing a small amount of fluid (0.2 c.c.), one may obtain pure blood with apparently no marrow cells present. It is possible that one aspirates the content of a sinusoid.

In previous experimental work where the marrow samples from different bones were examined shortly after sacrificing the animals and no admixture of blood was possible, we found strikingly coordinated changes in different portions of the marrow examined.²⁻⁶ Human marrow samples taken from different portions of the marrow shortly after death, without the possible admixture of blood, exhibited also a markedly similar cellular pattern.¹ In the enumeration of the total number of nucleated marrow cells, the clumping of the cells to each other or adherence of the cells to bony spicules may produce discrepencies.

The third possibility for the numerous differences is the lack of homogeneity of the bone marrow. Custer¹⁴ has shown that the cellular density of the marrow of the long bones may vary enormously in even closely adjacent regions and that the flat bones may be densely packed with cells, while the fatty marrow of the long bones may contain but few groups of cells with hematopoietic potency. Recently, Reiter⁵ pointed out that there are irregular fatty areas present in the actively functioning red marrow of the sternum. Helpap,⁷

iter,⁸ and Jeanneret⁹ claimed differences in the cellular composition in different portions of the marrow.

The long bones of man and mammals usually contain yellow fatty marrow which there are scattered centers or islands of hematopoietic cells. However, comparative studies of the bone marrow of flat bones and different portions of the long bones revealed the same trend in the relative percentage distribution of the hematopoietic cells in dogs and monkeys.^{2, 3}

Our Cases 8, 14, and 19 illustrate clearly that probably there are irregular areas of fatty tissue in the red marrow also, with marked difference in fat content simultaneously obtained sternal marrow samples. In spite of the numerous differences between the cells in the two simultaneously obtained marrow samples, the trend of the cellular differentiation is the same. This fact is illustrated in Tables I to III by the myeloid-erythroid ratios. If at one portion of the marrow erythroid cells are proliferating, then another portion of the marrow will reveal similar erythroid stimulation. In stem cell leukemias, and in lymphatic leukemias there again was a remarkably similar increase of the abnormal cells counteracted in the different samples. Even in the primary or secondary neoplastic processes of the marrow, with the formation of more or less circumscribed nodular areas, the uninvolved portions of the marrow reveal similar cellular population.
